Normative and Ethical Considerations

Ethnomethodology has been criticized for treating normative aspects of the activities studied as 'mere phenomena'

(Habermas, 1984: 106). Such criticisms may seem to have a point, for example, when Charles Goodwin (1994) in a much-cited article draws a parallel between discursive, gestural, and inscriptive practices used in an archeological dig to instruct novices on how to see a key structure in layers of soil, and those used by the defense in a famous trial to persuade a jury on how to see a videotape that appeared to show a group of police officers relentlessly and violently beating a prone suspect. The defense attorney and witnesses used various visual props and testimonies successfully to persuade the (notoriously credulous) jurors to see the police actions as instances of normal and legitimate professional practice. Goodwin does not overtly condemn or endorse the rhetorical use of such practices, but instead describes them in detail from a detached point of view. However, the lack of any explicit ethical evaluation in Goodwin's article does not reduce normative considerations to mere phenomena or arbitrary constructs; instead, his article effectively provokes a reader's response without need for explicit commentaries, principles, or rules instructing readers on how to respond. His descriptions of the trial testimony present the adversaries' displays and specifications of the police actions; contrastive accounts and demonstrations that incorporate normative judgments and ethical claims. Instead of recasting such judgments and claims in terms one or another transcendent ethical framework, Goodwin displays and explicates the way normative judgments were produced, addressed, and fought over by the parties in the trial court. He thus allows readers to draw their own judgments from a rich body of materials, rather than preempting such judgments with a theory or set of general principles. Accordingly, when ethnomethodologists investigate highly charged uses of, and appeals to, normative judgments, they enable readers to examine specific configurations of action and judgment that do not neatly fall under recipe versions of norms and values. Rather than invoking or developing a general normative theory, ethnomethodologists invite their readers to consider intricate situations of practice and contestation that no single general framework can possibly forecast or resolve.

Practical and ethical dilemmas are no less salient for ethnomethodologists than for cultural anthropologists, lawyers, and other students of, and participants in, the activities that give rise to such dilemmas. The policy of ethnomethodological indifference does not relieve the investigator of ethical choices and responsibilities. Like other investigators, ethnomethodologists should in some circumstances find it advisable to respect norms of privacy and propriety, while in others they may be compelled to expose wrongdoing. However, as a body of concepts, research policies, and exemplary studies, ethnomethodology does not supply a set of rules or ethical guidelines for making such difficult choices. This does not mean that ethnomethodologists are unethical, but that their ethical judgments have a broader existential basis than the specific doctrines and lessons furnished by participation in an academic field; they have what Hutchinson et al. (2008: 36) call a life-long 'extramural' basis in communal living, and are not derived from a particular academic school, theory, or method.

Laboratory Studies, Constructivism, and Actor-Network Theory

Ethnomethodology has been explicitly acknowledged for its contributions to two major developments: one in science studies, in connection with of series of ethnographic studies of scientific laboratories (commonly known as laboratory studies) starting in the late 1970s; and the other in connection with on-site investigations of technical activities in high-tech workplaces starting in the mid-1980s. Important initiatives for both of these developments came from a research program that Garfinkel called 'studies of work' (1986). Such work included practices associated with specific occupations and professions in the arts, sciences, and many other fields, but it also included commonplace activities of many kinds, such as driving in traffic, recreational pursuits, and household routines. The idea of conducting ethnographic studies of work was far from novel at the time, but what Garfinkel proposed was distinctive: to study the production of practical actions that make up the technical contents of work (playing musical instruments, conducting experiments, proving mathematical theorems, navigating vehicles in traffic, etc.) (for recent collections see Rouncefield and Tolmie, 2011; Tolmie and Rouncefield, 2013).

This aim to engage with technical contents contrasted with the deliberate neglect of such contents in most previous ethnographies of work, in favor of investigations of the social backgrounds and lifestyles of the actors, the systematic social functions of the action, the cultural supports of the activity, and so forth – virtually everything 'social' about the work except for the situated interactional production of the work itself. This agenda happened to coincide with the question Bloor raised at the very start of his *Knowledge and Social Imagery* (1991 [1976]: 3) to set up the Strong Program's agenda: "Can the sociology of knowledge investigate and explain the very content and nature of scientific knowledge?"

Ethnomethodology and Constructivism

By the end of the 1970s, several sociologists of science had conducted extended on-site observations of laboratory activities and they answered Bloor's question with an enthusiastic 'Yes' (Latour and Woolgar, 1979; Knorr Cetina, 1981, 1983). Not only did they answer affirmatively, but they also presented arguments and observations to support the idea that specific natural scientific facts were constructed in and through laboratory practices and interactions.

What exactly was meant by construction or social construction, and whether or not it undermined trust in the reliability of scientific practices and the solidity of scientific results, remained (and remains) ambiguous and confusing. Often, but not always, it meant that scientific results were fraught with uncertainty, that the process of scientific investigation was subject to unanticipated contingencies, and that highly artificial conditions that were set up to control such contingencies – conditions so thoroughly artificial that the laboratory was the last place in the world that one could hope to find raw 'nature.'

The early laboratory studies by Latour and Woolgar and Knorr Cetina assimilated selected themes from

ethnomethodology into constructionist arguments, but other ethnomethodologists preferred then, as now, to speak of the production rather than the construction of natural and social orders (Lynch, 1993; Button and Sharrock, 1993). While it may be so that no fact is ever free from human intervention – or construction in the broadest sense of the word – local uses of the term in empirical science (though not in mathematics and certain branches of theory) refer to research artifacts that are distinguished from natural objects (Lynch, 1985). Ethnomethodologists prefer not to speak indiscriminately of the construction or manufacture of knowledge, and prefer instead to maintain an indifferent orientation to the way distinctions between constructed and unconstructed realities are employed in practical action and situated argument. One could say that, instead of resolving all scientific facts and findings on the side of artifacts, ethnomethodologists take a symmetrical view of scientists' working distinctions between constructed and unconstructed phenomena.

The boldest claims made in laboratory studies licensed a tendency that has remained widespread in STS, which is to view any and all naturalistic claims with skepticism, and to treat references to science, objectivity, facts, and consensus as deliberate or disguised rhetoric that lends authority to ontological claims. Such claims and tendencies have drawn considerable attention (both negative and positive) to STS in the past three decades, though central figures in the field, for different reasons and in different ways, have backed away from the more florid constructivist claims (Collins and Evans, 2002; Latour, 2004). Although sociologists and anthropologists of science, technology, and medicine continue to conduct ethnographies, for the most part constructivism is now 'black boxed' (to use a common STS idiom), so much so that the word no longer provokes much interest, and the ideas that scientific facts have no special epistemic status, and that scientific work is messy and fraught with contingency, are more often assumed than critically examined. Nevertheless, exactly how these studies lend empirical support for the philosophical and political arguments that so often cite them remains very much in doubt (Doing, 2008).

Ethnomethodological studies of mathematics (Livingston, 1986; Greiffenhagen and Sharrock, 2011), and scientific observation and laboratory work (Garfinkel et al., 1981; Lynch, 1985), are often mentioned together with constructivist studies, but there is a clear difference in the overall point of the studies and the claims they make on their own behalf. The aim is not to answer Bloor's question with documented arguments to the effect that natural science and mathematics are constructed, but to show how specific proofs, observations, experimental protocols, and so forth, are produced, assessed for their adequacy, reproduced, disseminated, disputed, and agreed upon in specific laboratories and other communicative fields. Whether or not such work supports a constructivist philosophy, or suggests that science is inherently messy and political, is a matter of indifference. Consequently, though occasionally recognized and appreciated in STS, ethnomethodological studies tend not to provide clear support for general theoretical or normative programs, whether constructivist or not. This lack of clear resolution may be disappointing to some readers, but it motivates continued investigation of work in the sciences and mathematics, but not in order to document a constructivist (or other) philosophy of science, but to address basic questions that earlier studies claimed to resolve about the nature and content of science while leaving many stones unturned (Sormani, 2014).

Ethnomethodology and Actor-Network Theory

As mentioned earlier, there are points of affinity between ethnomethodology and actor-network theory (ANT) – a theory, or rather an ontology that for at least the past two decades has been strongly established in STS. Latour (2005: 54n.) goes so far as to say that it "would be fairly accurate to describe ANT as being half Garfinkel and half Greimas" (the latter being semiotician A.J. Greimas). As mentioned earlier, one point of agreement has to do with the conception of reflexivity, not as the scholar's or metaphysician's rare ability to reflect insightfully upon the motivations and social circumstances that the unreflexive actor fails to recognize or acknowledge, but as an intrinsic aspect in the field of action itself. More generally, there is agreement that, as Latour puts it, "it's not the sociologist's duty to decide in advance and in the member's stead what the social world is made of …" (2005: 29n.). Instead, the idea is to follow how the members assemble the social world, and not as a discrete domain separate from nature to be studied by social scientists. Moreover, like Garfinkel, Latour acknowledges that the conceptual and methodological instrumentarium offered by sociology simply cannot keep pace with the varied and nuanced, not to speak of handsomely resourced, practical and discursive maneuvers that it would hope to comprehend and explain.

There also are some clear differences. Whereas ethnomethodology, at least in principle, relentlessly eschews transcendental analysis, Latour turns to semiotics to gain leverage on how locally situated actions manage to transcend their circumstances. The transcendence is achieved via texts and related literary technologies and infrastructures that afford the collection, stabilization, movement, analysis, criticism, and reconstruction of communicative actions. Latour's grander (albeit often deflationary) philosophical writings on modernity show a willingness to ride the literary mobile to span vast territories. In contrast, Garfinkel was highly distrustful of textually conveyed journeys, and he expressed this distrust through a repeated insistence that practical action and practical reasoning take place only deceptively in texts, and that sociology is doomed to be a 'literary enterprise' by virtue of its almost exclusive reliance on documents, textual instruments (surveys, transcripts, and the like), coding schemes, and stories, both as data and as exhibits of analytical work. He even distrusted the literary technologies of tape recording and transcription that so many ethnomethodologists use for their own analyses of 'naturally organized' activities. This distrust also may have contributed to his convoluted prose, and his reluctance to complete and publish many of the writings he had drafted and outlined.

At times, such denigration of texts and literary enterprises may seem to express a quixotic desire to reach beyond the literary form that gives expression to that very hope to grasp the things themselves, just as the eschewal of theorizing may seem itself to be theoretically framed. However, the deceptively simple theme of instructed actions suggests a different picture. Far from ignoring or denigrating texts and formal analysis, the phenomenon of instructed actions pairs and blends formal

analysis with a counterpart: courses of action that recurrently make use of, supplement, and selectively consult and disregard instructions. Examining instructed actions by performing and describing specific efforts to follow a given set of instructions, directions, or plans does not aim to reveal that formal instructions always turn out to be inadequate. Instead, the aim is to show whether or not, and how, they become adequate in singular courses of action, and to identify what else such action involves. Just how they are used in action is the thing itself of interest to ethnomethodology.

The puzzling issue raised by Latour's effort to combine Garfinkel with Griemas is that the latter's story grammar is just the sort of general abstract schema that studies of situated actions tend to dissolve (see Lenior (1994) for a critique of Latour's use of Greimas; and Alac (2011) and Liberman (2013) for different ways to integrate semiotics with ethnomethodology). One aspect of Garfinkel's suspicion of textual form is that the analysis of texts (such as with a coding scheme or program) draws equivalencies between apparently similar linguistic figures and syntactic positions in diverse narratives, with very thin regard for contexts of use that can easily dissociate what appears to be equivalent on paper. The much debated move that Latour makes when he creates a second axis of symmetry seems, on the one hand, to be a radical move to make all 'actants' (agents of action described in a narrative) equivalent, regardless of their status as human (a person), collective (a government agency), or nonhuman (a disease agent). This radical move of inviting all manner of entities into the 'actor' category may seem to avoid the problem created by the oversocialization of nature and technology that Latour attributes to the sociology of scientific knowledge. On the other hand, the apparent equivalence between these actants is a formal equivalence that recalls the classic Saussurean distinction between stable elements of language and fluid combinations of those elements in speech. For Latour, it seems, Garfinkel articulates the fluidity of syntagma (an elementary constituent element of a text), while Griemas gives him a vocabulary and system for stabilizing narrative elements in a network. The problem is that the former threatens the stability and seeming transcendence of the latter, so that the one axis deconstructs the other. Latour has shown an admirable willingness and ability to think outside the box (or, rather, the semiotic square), including boxes of his own creation, but semiotics has provided an abstract anchorage (if that is not an oxymoron) for ANT. Perhaps ethnomethodologists should envy such anchorage, in preference to what Garfinkel facetiously called, during lectures and unpublished presentations, his "boat without a bottom" – inviting his critics to go ahead and "throw your rocks, they'll fall right through." However, rather than anchoring ethnomethodology in an abstract system, Garfinkel suggested instead that ethnomethodological studies of work could hybridize with an open variety of other fields. Some success on that front was achieved in studies of information technology.

Ethnomethodological Studies of Technical Practice

A variant of the theme of instructed actions – plans and situated actions – proved to be immensely important for launching an offshoot of ethnomethodology and STS that became established both in academic research on information technology and in corporate research centers where such technology is designed. Lucy Suchman (2007[1987]) creatively worked with the theme of instructed actions to observe and critique the investment in formal plans in cognitive science and artificial intelligence. Her research took place at, and was supported by, the Xerox Corporation's Palo Alto Research Center, and involved detailed recording and analysis of users' efforts to comprehend instructions conveyed through an interactive display panel on an (at the time) advanced photocopier. Suchman described the all too common confusion experienced by users (some of whom struggled hilariously to make photocopies with the smart machines), and such observations led her to develop a critique of programmed instructions that took little account of the situated actions of users who, typically, did not notice, attend to, or fully comprehend what the programmed instructions were telling them to do. Part of the problem, according to Suchman, was that machine instructions were designed along the lines of computer programs in which following instructions was viewed as a matter of mechanically executing plans, rather than engaging with a machine in an embodied way, in the midst of the distractions and variations in technical skill found in particular organizational environments. Drawing from ethnomethodology, STS, and cultural anthropology, Suchman pointed to the contingent, circumstantially relative way that formal plans, rules, and instructions relate to situated actions.

Xerox, Microsoft, and other corporations that maintain research centers were convinced by Suchman's and other ethnographers' research to support in-house groups of ethnographers to advise and collaborate with design teams to better take into account the potential fate of their programmed innovations when placed in the hands of users in offices and homes. This research not only found a home in industrial research centers, it also became highly important for interdisciplinary academic fields in communication and information studies, such as computer-supported cooperative work, human–computer interaction, and workplace studies (Luff et al., 2000). The hybrid was dubbed 'technomethodology' by Dourish and Button (1998), and while it has been a success in many respects, a point of contention among some of the key participants in the emergent field has been the tendency to use hybrid studies as a basis for reverting to the familiar social science theories, arguments, and disciplinary ambitions that such studies were designed to bypass (Crabtree et al., 2009).

One particularly difficult challenge for ethnomethodological studies of highly technical activities is to contend with the 'unique adequacy' requirement (Garfinkel, 2002: 169). This is an extension and radicalization of the classical sociological requirement that an adequate description of human actions must take into account (must exhibit understanding of) the agent's purposive orientation. In studies of technical practices, the unique adequacy requirement assigns priority to the cultivated technical understandings of skilled practitioners, rather than to the descriptive language, conceptual frames, and metaphors creatively devised by social analysts who have not mastered the practice in question. To paraphrase J.L. Austin, the practitioner's account may not be the last word

on the subject, but it is the first word. However, just as technical language and skill presents an initial barrier to the novice who would master a practice, it also presents a barrier for getting access to, observing, understanding, and writing about practices – especially when the proverbial 'average intelligent reader' is unlikely to know much of anything about the practice. One way to contend with the problem of conveying technical contents to nonspecialist readers is to devise analyses and demonstrations of relatively undemanding cases – analogous to the way Wittgenstein uses examples from elementary arithmetic and geometry in his *Remarks on the Foundations of Mathematics*, and justifies these examples as no less authentically mathematical than more esoteric cases. One relatively small domain of ethnomethodological studies makes use of historical cases such as Galileo's pendulum and inclined plane demonstrations, elementary school science lessons, and devised exercises using geometric patterns and easily purchased prisms (Garfinkel, 2002: Chapter 9; Bjelic, 2003; Livingston, 2008; Lynch and Macbeth, 1998). Such studies certainly do not grant access to cutting edge science and mathematics, but they do provide a way to contend with (both in writing and in embodied exercises with students) the contingencies of handling and improvising with equipment. They also enable readers to depart from textual accounts and interpretations, to gain first-hand access to struggles with how to see phenomena: to examine their own work of following instructions in novel situations, and to experience the frustrations and delights associated with embodied practice.

Abstract

The interdisciplinary field of science and technology studies (STS) has only emerged in the late 1970s but has been influenced by various lines of thought in sociology, philosophy, and economics. At its basis is the claim that not only the social institution of science or the impact of technological change on society is open to social analysis but also the very content of science and engineering, i.e., scientific facts and technological objects. This article sketches out the development of STS from its roots, among others in the sociology of knowledge and history of technology, to contemporary issues such as the problem of expertise and transformations in the production of knowledge.

Introduction

Science and technology studies (STS) have emerged in the 1970s and 1980s as a distinct interdisciplinary field – or intradisciplinary as Jasanoff (2010) puts it to stress its focus on questions not raised within existing disciplines – which deals with the inseparability of science and technology from social structures and practices. The constitutive idea in contrast to its precursors in the sociology, history, or economics of science and technology is an understanding that also the content of science and engineering (scientific facts, technologies, objects) is open to social analysis and not the result of a privileged form of knowledge about nature. Facts and artifacts are but temporarily stable outcomes of heterogeneous activities of scientists and engineers and their entanglement in wider social and political relations. From a STS perspective sociotechnical assemblages are the smallest units of analysis and cannot be simply split into preexisting social and material dimensions, which are then analyzed separately. Society and technology/materiality coconstitute each other and mutually shape each other through processes of translation, inscription, and enactment. At its best, STS thus not only contributes to a more appropriate understanding of science and technology but also of society.

There are no strict demarcations of what counts as STS and what is already outside its realm. One may take a narrower view on the formation of core concepts and emerging disciplinary structures, or a broader view on STS as a multifaceted and heterogeneous field overlapping with, e.g., economic innovation studies, anthropology or cultural studies, and also comprising of a broad range of problem- and application-oriented STS research on health, climate change, or the democratization of science and technology. This article takes the broader view and complements the formation of an academic canon with the development of an 'engaged program' of STS (Sismondo, 2008). A number of introductory textbooks (e.g., Fuller, 2007; Hess, 1997; Sismondo, 2010; Yearley, 2005) as well as articles on the history and development of the field (e.g., Jasanoff, 2010; Latour, 2004; Pestre, 2004; Woolgar, 2004) along with the STS-related entries in earlier versions of this encyclopedia have already contributed to an ex-post consolidation and ordering of the field (and at the same time self-critical reflection on such attempts). This article builds on these contributions and – given the heterogeneity and ongoing dynamic of the field – presents a somewhat eclectic selection of further lines of thought and reasoning.

Precursors of STS

Science and technology have been an object of social sciences and humanities for a long time and various approaches and schools of thought have led up to the current concepts used in STS. Science has been regarded a crucial element in processes of modernization and the rise of a capitalist economy, as, e.g., expressed in the writings of Karl Marx or Max Weber. Only later, science and knowledge generation became direct objects of social scientific research, as in Karl Mannheim's sociology of knowledge and in the investigation of science as a social system in Robert K. Merton's work. Technology also has played a long-standing role in the social sciences and humanities, whether in social history (Mumford), political economy (Marx), or philosophy (Heidegger).

Science as a Social Institution

The development of a sociology of science is closely interwoven with the scholarly work of American sociologist Robert K. Merton. Merton analyzes science as a social phenomenon in at least three distinct ways (Barnes, 2007): (1) as a social unit functioning in a larger social system and being affected by the development of its social surroundings – as, e.g., analyzed in Merton's early work on the emergence of science in puritan seventeenth-century England; (2) as a set of peers, a moral community and a subculture with a distinctive normative order – Merton's work on the ethos of science expressed by four basic norms stands for this dimension of his work; and (3) the question of how the normative order in science is sustained by a specific reward system encouraging original research. Merton's article on 'The normative structure of science' (Merton, 1973[1942]) is probably his most popular and well-known contribution to the sociology of science and reflects the political context of the 1940s by emphasizing the importance of a democratic social structure for science to thrive and to let scientists live up to their ethos expressed by a set of four norms: communism (later termed communalism), universalism,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.03064-6

disinterestedness, and organized skepticism. The institutional goal of science depending on these norms is 'the extension of certified knowledge' pointing clearly to the assumption that 'science as a social phenomenon' only extends to the social behavior and practices of scientists but not to the content of science itself. This strand of a sociology of science has remained influential throughout the postwar period with often controversial discussions about the need for additional norms, their empirical validity, and relevance for the social analysis of the community, culture, and institutional makeup of science (see e.g., Zuckerman, 1988).

The Social Constitution of Knowledge

Another strand of sociological thinking preparing the ground for STS is the sociology of knowledge, best represented in the work of Max Scheler and Karl Mannheim – particularly in his book *Ideology and Utopia* (Mannheim, 1929). The key argument is that knowledge is conditioned by the social position of the person or group who formed these thoughts. Everyone's belief and possibility to know depends on the social context he/she is immersed in, be it social class, religion, profession, or age cohort. Obviously, such a position has to deal with both (Heintz, 1993), the problem of relativism (no overarching criteria for the evaluation of knowledge claims) and reflexivity (as the positionality of knowledge also applies to the social scientist). Mannheim sought an answer to relativism in the 'multiperspectivity' of different knowledge claims and the aim of sociology of knowledge to understand why and how these different perspectives and knowledge claims differed. His strategy to deal with reflexivity, however, sets Mannheim apart from the later STS, as he chooses to exclude science and mathematics from the program of a sociology of knowledge and assign them a privileged epistemological status. His contemporary Ludwik Fleck (see next section) developed precisely such a program of a sociology of scientific facts.

History and Philosophy of Science and the 'Structure of Scientific Revolutions'

Thinking about the constitution and development of scientific knowledge has long been a prerogative of epistemology and the philosophy of science, which upheld the special status of scientific knowledge and its exclusion from sociological or historic analysis. However, not least developments within the theory of science paved the way to historic analyses of the development of scientific knowledge by Thomas Kuhn and others. Two core theses set the scene for the so-called anti-positivist or historic turn in the philosophy of science: the underdetermination of scientific theory as argued by Pierre Duhem and W.V.O. Quine and the theory-ladenness of observation. If isolated theoretical hypotheses cannot be simply falsified by contradictory observations and if theory and observation cannot be strictly separated, historic or sociological arguments need to stand in to explain the development and constitution of scientific knowledge. This program has been taken up in the book *The Structure of Scientific Revolutions* by Thomas S. Kuhn (1962) who (despite being criticized on various grounds) created an intellectual space for STS analyses of the social constitution of scientific knowledge. Kuhn essentially made an argument against the linear and cumulative growth of scientific knowledge and illustrated with various cases from the history of science, how scientific development is characterized by (rarely occurring) shifts in scientific paradigms ('scientific revolutions'), which are shared within a scientific community and incommensurable with each other. By far the largest part of scientific activity ('normal science') is engaged in problem solving within the framework of an existing paradigm. Seen from an STS perspective, one can distinguish between a more radical and a more conservative interpretation of Kuhn's work (Pinch, 1997). This is particularly visible in the use of the concept of paradigm either as a description of a shared social activity or social network in science (similar to an 'invisible college') distinct from the cognitive dimension of science, or as a term emphasizing the combined sociocognitive nature of science, i.e., science understood as doing and practice. Kuhn's work also laid the ground for a rediscovery of Ludwik Fleck's (1979[1935]) book on *The Genesis and Development of a Scientific Fact* where Polish medical doctor Fleck developed his concept of 'thought collectives' and 'thought style' and a concept of scientific truth relative to these social collectives, which anticipated much of STS and social constructivism in a more contemporary way than Kuhn's writings, which took most of the credit.

The Social Impact of Technology

While the sections above sketched out different lines of thought about science as a social phenomenon, sociological and philosophical engagement with technology and artifacts took place rather separate from these approaches. The main thrust of theses approaches was to understand the impact of modern technology on society and – going beyond a one-sided relationship – the interdependence of changes in social structure (or: civilization) and technological development. Lewis Mumford and Jacques Ellul can exemplarily be mentioned in this context. In *The Myth of the Machine* Mumford (1967) develops a universal history of civilization with the development of order as the pervasive formative principle. As he points out with examples of megamachines such as pyramids, but also polytechnic traditions of medieval times, the 'idea' of the machine is deeply entrenched in the history and development of civilization, in its organization but also its ethics and aesthetics. For Jacques Ellul too, human history and condition is intricately interwoven with technology. However, where Mumford puts some hope in alternative (democratic) technological traditions, Ellul draws a more pessimistic picture of technology taking control of modern society. And similar to Mumford, 'la technique' is more than just machine technology – it is any complex of standardized means to attain predetermined results. "Technique integrates the machine into society. It constructs the kind of world the machine needs and introduces order (…), clarifies, arranges, and rationalizes. (…) It is efficient and brings efficiency to everything" (Ellul, 1964: 5).

Undoubtedly, various other lines of inquiry can be identified, which prepared the ground for understanding artifacts as being deeply intertwined with social, cultural, and political phenomena. Important inputs have, e.g., come from the sociology of industrial organizations (e.g., studies of the industrial

workplace and its interrelations with technological change); the economics of innovation and technological change (such as the work of Joseph Schumpeter and its later uptake in theories of evolutionary economics); or early sociological analyses of the social and cultural factors that shape technical invention (e.g., Gilfillan, 1935).

The Emergence of a New Field

Only in the late 1970s and early 1980s, a new field of scientific inquiry took shape, which later came to be known as 'STS' – though terms such as 'Social Studies of Science and Technology' or 'Science, Technology, and Society' existed in parallel and are sometimes still used. The common focus of early STS was to gain an understanding of the 'social fabrication' of scientific facts – be it as a product of discourses, social interests, or the heterogeneous social practices involved in producing scientific knowledge. Much of the ground for this new line of inquiry was prepared by Kuhn's writings and a 'linguistic turn' inspired by Ludwig Wittgenstein's philosophy. Two sets of approaches stood at the center of early STS: the sociology of scientific knowledge (SSK) and ethnographic studies of scientific knowledge production in laboratories. In both cases, the focus was on natural sciences, which represented the 'hardest possible case' to show how scientific knowledge was imbued with social and cultural influences and did not constitute a separate, asocial, and ahistoric realm of positive knowledge.

The Sociology of Scientific Knowledge

Two UK 'schools' stood at the center of early debates about the social construction of scientific knowledge: a group of researches at the University of Edinburgh (David Bloor, Barry Barnes, Donald MacKenzie, Steven Shapin, and others) developing the 'strong program' as well as interest theory of scientific knowledge, and a group at the University of Bath (Harry Collins, Trevor Pinch, and others) with their 'empirical programme of relativism' (EPOR) and a focus on the analysis of discourses and scientific controversies. The 'strong program' was based on several methodological claims for a more symmetric analysis of scientific knowledge generation – meaning that empirical analysis should be ignorant to whether a scientific claim was true or false (contrary to the philosophy of science approach, which is just about ways of evaluating the truth or falsity of such beliefs). The aim thus was not to methodologically decide on scientific truth claims, but to understand how they emerged, were accepted or rejected in social interactions. Historical case studies, moreover, elucidated how decisions about scientific beliefs and knowledge claims were influenced by wider social interests ('interest theory'), e.g., how statistical concepts originating in early twentieth-century England were ultimately grounded in debates about eugenics (MacKenzie, 1978). Instead of searching for such 'external social factors' the Bath school with their 'EPOR' along with scholars such as Michael Mulkay rather focused on processes of inner-scientific discourses and controversies to understand how interpretations of scientific facts were developed, rejected, or stabilized.

Laboratory Studies

Along with the SSK, another more ethnographically inspired field of research developed around the analysis of knowledge production in scientific laboratories. Key representatives of this approach were Bruno Latour, Steve Woolgar, Karin Knorr-Cetina, and Michael Lynch. Not 'science as knowledge' was at the center of these studies, but 'science as a localized practice,' which was analyzed through participant observation and the analysis of documents and discourses at the locus of knowledge production, the scientific laboratory. As Knorr-Cetina (1995) points out, these studies showed how scientific objects were not only 'technically' manufactured in laboratories but also symbolically and politically construed. Scientific knowledge thus is not only embedded in controversies and wider social processes, but also socially fabricated in concrete locales with their specific knowledge cultures and idiosyncrasies. Particularly, Bruno Latour and Steve Woolgar in their study *Laboratory Life* (Latour and Woolgar, 1979) do not focus on concepts of intentionality, but rather on the detailed description of the gestures and action observed in scientific work (Pestre, 2004). Scientific facts are not correspondents of observation, textual representation, and things, but gain 'reality' only through series or networks of translations that can each be contested and renegotiated. Particularly, Latour's study on Louis Pasteur, 'Give me a laboratory and I will raise the world' (Latour, 1983), makes clear, how laboratory practices transcend the boundaries of the laboratory and modify social order and eventually transform the world.

The Technological Turn in Science Studies

During the 1980s, the program of understanding the social fabrication of scientific facts was extended to the study of technology. Central to these concepts is that there are potential choices (not necessarily conscious and manifest ones) inherent in the design of artifacts and technical systems. There is no inherent and compelling logic of technical development; the choices made depend on organizational, political, or economic factors and on actor-strategies.

The Social Construction of Technology

In their article 'The social construction of facts and artifacts: or how the sociology of science and the sociology of technology might benefit each other,' Trevor Pinch and Wiebe Bijker (1984) apply the methodological principles and strategies of the 'EPOR' to the study of technological innovation. Their aim is to understand technology 'from inside,' as a body of knowledge and as a social system. This may be achieved (following EPOR) by a symmetric and impartial treatment of technical artifacts without an external reference in deciding why one technology works and another one does not. At the basis is the concept of interpretative flexibility, meaning that technologies are open to more than one interpretation by different relevant social groups; the existence of social mechanisms that lead to a closure of the controversy at a second stage, and finally the relation of such closure mechanisms to 'the wider context,' which they call the technological frame to contrast the

contingency and to an extent arbitrariness of interpretative flexibility. Along with the historic analyses of the messy and nonlinear ways of developing artifacts inspired by the Social Construction of Technology approach, another historian of technology gained an important influence on the social understanding of technology. In his seminal work *Networks of Power* Thomas P. Hughes (1983) demonstrated the fundamental inseparability of the social and the technical in the analysis of artifacts in his historic analysis of the development of the electricity system in the US, the UK, and Germany as an example of other 'large technical systems' and infrastructure technologies. Efforts of system building as a heterogeneous social, economic, and technical ability stood at the center of this analysis, but also the momentum and obduracy gained as such large sociotechnical ensembles mature and become increasingly entrenched in society and material structures.

Actor-Network Theory

A second direct line from science to technology studies is established by actor-network theory (ANT) – closely linked to the names of Bruno Latour, Michel Callon, and John Law – who already studied science as a practice of creating heterogeneous networks of actors, inscriptions, theories as well as scientific instruments and other artifacts and accordingly put forward the notion of 'technoscience' to stress the increasing convergence of producing scientific knowledge and technical objects. ANT follows the consequences of the 'new' social studies of science approach, especially its transgression of the separation of an internalist and externalist analysis of science to its radical end. If the social realm of subjects and the realm of scientific facts or things is not separable and reducible to each other any more, if neither nature nor society are objective arbiters, social theory has to be rebuild and conceptualized in a way that simultaneously includes humans and things. This results in a generalized principle of symmetry between human and nonhuman actants (as a term for anything that has force to change things), famously put forward in Michel Callon's (1986) article on the scallops of St. Brieuc bay, which are as much granted agency as the scientists or fishermen struggling with a solution to cultivate such mussels. The stability of human social assemblage is always shared with the nonhumans mobilized to this end. The same holds true the other way round: what we call things or scientific facts are also highly impregnated with sociality and need constant work to stabilize – as Latour once called it: technology is society made durable. Central terms employed to explain the eventual constitution of these heterogeneous assemblages are 'translation' signifying an active element in the network connections as an enrollment into an actor-network always involves displacements and changes in the identity of actors; or 'heterogeneous engineering' as the tactics of network-building, which depends on the interrelation of a range of disparate elements of varying degrees of malleability. Though frequently at the center of controversies within science studies or criticized from outside (e.g., in the so-called 'science wars,' pitching so-called 'postmodernists' against 'scientific realists' or constructivism against objectivity in science), ANT still is at the center of much of the research carried out in STS and has not lost its provocative power.

Toward an Engaged Program

Building on and extending these core approaches of STS and crossing over with other theories and research fields such as cultural studies, history or gender studies, STS has developed into a versatile and heterogeneous research field. Many of these subfields and specialties, however, have in common that they share an engagement with critically analyzing and deconstructing dominant social discourses and power structures enacted in sociomaterial relationships and reflect on the possibility of strategies and policies toward a more democratic, sustainable, or gender-equal society informed by such insights. The following section highlights a selection of these engaged approaches in STS.

Feminist STS

STS have had a productive relationship with feminist theory and perspectives since its beginning. Uncovering gender relations in science and technology and analyzing the role of science in legitimizing social forms of domination largely parallels the STS program of understanding the social construction of the content of science and technology. Feminist standpoint theory (e.g., Harding, 1991) claims that all attempts to know are socially situated and that the particular social position of women and their distinctive experiences of discrimination is not reflected in a male-dominated science. The social location of women and other oppressed can be an important source to increase objectivity in science. Donna Haraway takes this perspective further, particularly, in her seminal essay 'Situated knowledges: the science question in feminism and the privilege of partial perspective' (1991), where she develops a more dynamic and hybrid epistemology granting privilege to partial perspectives, which takes the position of the knower seriously. In her notion of situated knowledges, Haraway problematizes both subject and object and aims at thinking the world in terms of the 'apparatus of bodily production,' which brings her work in close interrelation with ANT and other STS approaches. Feminist positions have also been influential for the discussion of the social shaping of technology. As Wajcman (1991) points out, technology itself is imbued with male power and male interests, and technologies reveal a lot about the societies within which they are invented and used, about dominant images of social status and distributive justice, they currently reflect a male-dominated world.

From Epistemology to Ontology?

A recent issue of the journal Social Studies of Science asks whether one can speak of an 'ontological turn' in STS (Woolgar and Lezaun, 2013). In fact, important lines of discussion within feminist STS such as Haraway's above-mentioned 'situated knowledges' can be understood as a shift in analysis from different modes of knowing to different modes of being. Within this perspective, objects do not acquire a particular meaning through a given context, as Woolgar and Lezaun point out, but they are 'enacted in practices,' they are brought into being, or realized, in the course of a certain practical activity. What we perceive as things or social phenomena are not just

intertwined but constantly 'in the making' and the (temporarily stable) outcome of social and material processes. STS research does not just observe disembedded things, but performances, 'realities enacted into being,' as John Law puts it. Objects become ambivalent and fluid and various modes of enactment may bring about a multiplicity of objects, as, e.g., Annemarie Mol (2003) argues in *The Body Multiple* with respect to medical practices. In a similar vein, Karen Barad is concerned with the constitution of material objects in her concept of 'agential realism,' where materiality is understood as a practical achievement, a contingent upshot of practices and produced through intra-action in an apparatus consisting of bodies, norms, technologies, and other sociomaterial elements. If however, as Mol (2013) points out, realities are adaptive and multiple, if they take different shapes as they engage, and are engaged, in different relations, then questions of ontological politics become important and STS may create new normative concerns with the making-up of alternative worlds (see also Latour, 2004).

New Modes of Knowledge Production

During the past decades, STS have also increasingly turned to analyzing the changing role of science in economy, policy, and society. During the 1990s, a new phase of science-related policy has taken shape, where "basic research has become intimately intertwined with production of goods and technological development of relevance for all realms of society" (Elzinga, 1997). At the same time parts of science have undergone substantial transformations – addressed, e.g., with the notion 'mode 2' science (Gibbons et al., 1994) – characterized by a diversification of the locations of scientific knowledge production, an orientation toward problems that cannot be 'solved' by scientific research alone, require the participation of actors outside academia and are situated in a context of high uncertainty, and by demands for more social accountability and reflexivity.

STS interest has shifted accordingly to issues such as credibility (whose knowledge-claims are accepted as trustworthy?), expertise, the relation of science and policy, and the role of the wider public and civil society in science and technology. Science has become increasingly contested and at the same time plays an ever more important role in policy, court rooms the media or public controversies about various types of problems. STS analyses various sites of such contestation, such as the role of science in regulation and judiciary processes (e.g., Jasanoff, 1990), the influence AIDS activists got on the design of clinical trials for new AIDS drugs (Epstein, 1996), or patient groups on pharmacological research (Callon and Rabeharisoa, 2003).

This potential conflict between democracy and expertise is also discussed in terms of a 'problem of extension' by Collins and Evans (2002), i.e., the question who should legitimately participate in technical decision-making (see also Sismondo, 2010). Legitimate expertise extends beyond the provision of scientific knowledge and encompasses other forms such as contributory or interactional expertise, which facilitates meaningful interaction between experts and nonscientific groups. As Sheila Jasanoff highlights with her concept of 'civic epistemologies' (Jasanoff, 2005) such science–policy interactions crucially depend on, and interact with, political culture and must conform to established ways of 'public knowing' in order to gain broad-based support.

Moreover, STS approaches have increasingly become involved in studying and understanding various other contemporary social and political issues and challenges, such as climate change and the transition of systems of mobility, energy, or agriculture toward greater sustainability, the functioning of financial markets and wider processes of marketization and valuation, or the governance of innovation and technological change to name but a few of the pathways an engaged program of STS is currently taking.

Abstract

The problem of how to integrate expert knowledge with democratic politics has preoccupied scholars for more than a century but has become highly salient for Science and Technology Studies (STS) scholarship in recent decades. Political controversies over climate change, genetically modified organisms, and many other topics involve factual claims and counterclaims that invoke expert – and often scientific – authority. Much of the research in recent years on public engagement with science emphasizes the fallibility of expert knowledge and the hazards for democracy when scientific authority is overextended. At the same time, some scholars see a need for STS scholarship to develop a basis for distinguishing authentic expertise from non- and pseudo-expertise. Lively debates over these matters call attention to the extent to which public deliberation is adequate to the task of contending with, seemingly, technical matters. A key issue remains – how to define a purely technical, expert question, in public issues?

Introduction

Expert and expertise are commonplace words, but who counts as an expert and what counts as expertise (along with the often-neglected question of which issues require expert input) can be highly contested topics in many technical, political, legal, and ordinary situations. Expert claims themselves are frequently, perhaps even typically, contested, which itself generates questions over who is a legitimate expert. Some key institutional arenas, such as courts in the USA and UK though not continental Europe, use legal proceedings that depend upon formal adversary mechanisms for expert testimony. In many other social and political arenas, expert disagreement is often lamented as a cause of paralysis or uncertainty, where decisive commitment is sought. In some national systems, expert advice for policy is organized so as to be consensual, thus disallowing expert disagreements or at least, relegating divergent expert views to unofficial, 'critical science' status. Designated experts have important roles in law and governance, and the issue of how scientific expertise is defined and used in legal and governmental settings is a lively area of current Science and Technology Studies (STS) research, one with 40 or so years of history (Nelkin, 1979; Wynne, 2010 [1982]). This large and dynamic field has also studied, in depth, the varying reasons for expert controversy in countless substantive fields from climate change to contraceptives or genetically modified (GM) crops and foods. Review-based studies from STS (Cambrosio and Limoges, 1991) have noted that expert *disagreement* is natural and that expert consensus is a social achievement that needs explanation. This contradicts the conventional wisdom that disagreement signifies pathology requiring the assumed mistaken or hidden-interest 'side' to be 'exposed,' which would then reveal the true basis of 'natural' expert-revealed consensus.

As is the case with the word 'scientist,' the word 'expert' in many social contexts is used both as a descriptive category and as a term of praise. Once attained, expert credentials can launch lucrative careers and confer respect and influence. In important areas of law, politics, and everyday life, experts are granted special authority. Especially when paired with the descriptor 'scientific,' expertise in one field can sometimes be an advantage for being granted presumptive influence and authority in others. Indeed, as a general matter, the relevant question of 'Expertise *for what*?' (and further: 'Who has defined this question?') is all-too-rarely deliberated. In some contexts in which experts are called upon to give advice, their credibility is allowed to extend broadly: a scientist competent in a given area – especially, a Nobel laureate – may be treated as an authority on a wider range of basic scientific questions, including questions that hold social, ethical, political, and legal implications. In the case of a Pauling, an Einstein, or a Hawking, the person's reputation may transcend mere expertise and take on the larger-than-life, indiscriminate proportions of a genius (Mialet, 2012).

Expertise, nevertheless, is always circumscribed and more so than is normally recognized and examined. As a result, authority – for example, the authority to issue permits to release materials into the environment and thus, society – may unquestioningly be assigned where it is contested. Few, if any, recognized experts would profess to be expert in every subject and there are many cases of notable scientists who fail to transfer their authority from one field or topic to another. In some cases they have drawn criticism and ridicule for overstepping the limits of their expertise, such as when William Shockley, a physicist of materials who received a Nobel Prize for his part in the development of the transistor, made conspicuous efforts to promote eugenic programs and became notorious for helping to set up a Nobel laureate sperm bank.

This Shockley example of what we might call 'expert overextension' is typical of many others in contemporary public affairs. In general, there is probably too little open and inclusive debate as to what kinds of questions a given policy issue needs to have specialist answers to, and what kinds of experts – practical or formally certified – are most appropriate for addressing them. Such questions also require clarity about whether scientists or any other experts may be in a position to answer them (Stirling, 2010). In many domains of public policy, such as in risk assessment for regulatory decisions about new technologies, the disciplinary composition of officially

designated expert advisory committees to government has been much narrower than the public policy issue in question merits. This happens, for example, when expert advisory committees for chemical pesticides are composed of laboratory toxicologists, with little or no scientific expertise in ecology and no practical farming expertise at all. Irwin (1994) examined one such case of risk assessment and the UK policy decision on the herbicide 2,4,5-T in the 1980s. In that case, a farmers' representative described the scientific expertise to which the government had granted authority, as "cloud-cuckoo land, behind the laboratory bench" (see also Wynne, 1989). The European Environmental Agency (Horremous et al., 2002) published a collection of similar cases, with the formal proposal that such expert advice be made more systematically inclusive in order to avoid neglect of key specialist knowledge, including relevant practical nonscientific expertise such as in actual uses of pesticides.

In policy and media circles as well as in science, the representation of expertise is often rather wider than it is accurate in its attributions of authority. By contrast, as discussed below, legal procedures are often ruthlessly aggressive and quite indiscriminate in their deconstruction of the grounds of expert credibility (Oteri et al., 1982; Jasanoff, 1995).

Professions and Expertise

To acquire a reputation for being an expert in some areas of conduct, a person need not acquire professional status or acquire formal credentials, but many professions, recreational activities, and other pursuits institutionalize tests and formal certifications to mark degrees of expertise (Grand Master in chess, Black Belt in karate, professional law degrees and bar exams, etc.). While professional status does not necessarily mark a person as an expert, expertise tends to come with the territory in some professions, such as those of the physician, scientist, certified public accountant, fingerprint examiner, and so on. Certified practitioners can lose their credentials for incompetence and malpractice or for failing to maintain and renew them. Credentials themselves are subject to scrutiny, since a person can be defrocked as an imposter when discovered to have faked the necessary credentials, even if they apparently performed competently in the profession. In some circumstances such as cross-examination in adversary trials, challenging questions are raised as to whether a person who professes expertise really is an expert; but in many circumstances such expertise is taken for granted.

In order for membership in a profession to confer expertise, the activity itself must have credibility. Some credentialed activities (such as driving a motor vehicle after passing a test and obtaining a license) are deemed too ordinary to count as domains of expertise in societies with high automobile ownership. A driver cannot claim to be an expert, except in specialized or exceptional cases, such as professional racing, driving highly specialized vehicles, or training others to drive. Some entire fields of activity lack credibility in particular historical, social, or cultural contexts, regardless of a member's attainments within such fields. A person with a reputation as an experienced and highly capable astrologer is unlikely to be regarded publicly as an expert, except in social and historical contexts in which an astrologer's knowledge is regarded as credible. There also can be occasions in which an experienced astrologer's knowledge is sought even by those who do not believe in astrology, for example, in an investigation of common practices among astrologers. The same can be said for 'alternative' health practitioners such as homeopaths, in most contexts.

Expert status contrasts, on the one hand, with the inexpert standing in the respective domain of activity attributed to amateurs, novices, or others who may have credentials but are deemed not to measure up. On the other hand, expert status contrasts with the 'lay' status of those who simply lack knowledge of, and training in, the field – often because they have no interest in pursuing it. Whether or not they have had any prior experience with, or interest in, the relevant fields, laypersons frequently encounter problems in deciding whether to accept expert advice – advice from a physician about a surgical operation; advice from an investment broker about whether to invest in a particular stock; advice from an auto mechanic about an expensive repair; advice from experts delivered through the media about the health effects of various foods and medicines; the potential consequences of (not) entering into one or another military engagement; and the reality of, or the best responses to, human-induced global climate change.

In popular usage, the term 'technocrat' often refers to a leader or style of leadership akin to that of a bureaucrat: a managerial style that avoids bold, visionary, and risky decisions in favor of competent, tedious, and rational attention to precision and detail. In political theory, technocracy has a more systemic denotation as a name for a pervasive system of governance in which experts rule indirectly by feeding technical advice and information to titular heads of agencies and other managerial authorities who are not in any position to question the technicalities (Galbraith, 1967; Winner, 1978), even when these authorities also harbor political commitments (see Jasanoff, 2004). For example, government officials rely upon numerous forms of expert assessment: environmental impact statements; health and environmental risk assessments; cost-benefit analyses of proposed legislation or regulation; assessments of the effectiveness of a proposed weapons system; estimates of increments of atmospheric carbon contributed by existing coal-burning power plants. Although no single expert or group of experts controls government decisions, in a technocracy, expert advice carries increasing weight in all significant decisions; and political meanings and issues may be framed in ways that, by default, give scientific expertise more power than that of its purely technical warrant alone.

In the past two decades, another political concern about expertise has become prevalent in the United States and also in various other national and international arenas. This is a concern that, far from having too much influence over governance, well-informed technical experts have too little. This is particularly evident in contentions over anthropogenic climate change (Hulme, 2009) but similar concerns have been raised about many other public issues, such as school biology curricula, especially concerning the theory of evolution (Latour, 2004).

The Expert as a Legal Category

Experts in many different fields are frequently called upon to advise courts and governments (Smith and Wynne, 1989; Jasanoff, 1990, 1995; Risinger, 2001). Although many experts have scientific credentials, others are deemed to be expert by virtue of professional or experiential knowledge that can inform a court about relevant matters that are not part of common experience. In the United States and many other nations, an expert witness is permitted to testify about relevant knowledge acquired through education, reading, scholarship, and other sources of training and experience – rather than directly witnessed 'factual' matters. Another way of putting this is that an expert witness is permitted to testify about inferences as well as directly observed facts (though legal scholars recognize that it is difficult to draw the distinction in practice) and to testify to collective, professionally negotiated, and agreed-upon disciplinary expert 'truth.' A witness with the relevant professional credentials is permitted to give a trained opinion about such matters as the psychological or neurological competency of the defendant or the cause of a vehicular or other accident. An expert also can testify about specific items of evidence, for example, to declare that a particular suspect's fingerprints match prints collected from a crime scene. This has, more recently, also encompassed DNA evidence (Lynch et al., 2008). An expert also may be called upon to give an opinion about a profession, either from personal experience or academic research; to describe accepted procedures and methods of certification; or to cite statistical error rates for particular procedures. The normal state of knowledge or practice for a given scientific field at a given time, is also a matter of required expert testimony, where for example, negligence may be at issue and could be disproven if it were shown that the actions of (for example) a civil engineering designer-contractor at a given time, were in accordance with prevailing standard practice or scientific knowledge.

Representatives of a particular occupation or trade may also be asked to testify about matters that are collateral to their technical training: psychiatrists typically are asked to assess the future 'dangerousness' of a defendant (a legal category that is not specifically included in psychiatric nosology); a surgeon may be asked to comment on whether or not a victim's wounds would have been the cause of death; a dentist may be asked to advise a court about whether a bite mark on a victim matches the teeth of a suspect. In a classic law review article, Justice Learned Hand (1901: 46) mentions a historic case in which battle-tested sailors as well as physicians were asked for their opinions on whether a deceased person could possibly have drowned if the body had no water in the lungs. Scholars, including historians and STS scholars, occasionally testify about such matters as the history of fingerprint expertise, the scientific status of creation science and intelligent design, and whether or not tobacco smoking was generally known to be hazardous to health prior to recent decades when tobacco companies were promoting tobacco-smoking.

The problem with how to handle expert testimony in jury trials has preoccupied trial courts in the United States and elsewhere for the past century. This has included fraud trials, where the required financial expertise is extraordinarily esoteric. Although rules of evidence allow judges to summon experts to testify, usually they appear on behalf of one or the other adversary party, though in some European legal systems such adversary mechanisms are not used and experts are summoned by the court. The alignment of expert authority with partisan arguments creates a set of problems in jury trials (and also in bench trials, given the fact that judges generally do not have expertise in all or most of the specialties that feature in expert testimony). One commonly mentioned problem is that of a battle between experts, where juries are faced with choosing between contradictory testimonies but without the technical basis for making an independent choice. Another problem is that one side in an adversary trial often has an advantage over the other by having more resources for hiring expert witnesses with impressive credentials.

Uncertainty about the criteria for admitting expert witnesses in jury trials led to a series of landmark decisions by the US Supreme Court in the 1990s (*Daubert v. Merrell Dow Pharmaceuticals* [1993]; *General Electric v. Joiner* [1997]; and *Kumho Tire v. Carmichael*, [1999]). Admissibility decisions are rulings by trial judges about whether specific types of evidence – in this case expert evidence – should be presented to the jury. In a case in which expert evidence is critical, such as a class action lawsuit against a company for an allegedly unsafe product, a decision not to admit the plaintiffs' evidence can effectively shut down the case with a summary judgment before it goes to a jury. The Supreme Court's rulings in the 1990s drew a massive amount of discussion in law review articles, and also attracted the attention of STS scholars (Solomon and Hackett, 1996; Jasanoff, 1995). In the first and most famous of the cases, the Supreme Court in the *Daubert* decision addressed a question familiar to the philosophy of science: how to distinguish genuine science from pseudoscience or so-called 'junk science' (Huber, 1991). The Court famously listed four 'factors' or 'considerations' (they hesitated to use the word criteria) to guide judicial decisions about admissibility: testability, peer review, error rate, and general acceptance in the relevant field(s). The Court also qualified its recommendations with caveats about the need for judicial discretion. Nevertheless, the justices were criticized for imposing a one-size-fits-all conception of expertise on the immense range of specialties that can find their way into the courtroom (Risinger, 2001; Haack, 2005). The Supreme Court also was criticized for privileging stereotypical features of science, for assessing the admissibility of all forms of expertise, including technical and experiential evidence that makes no claim to scientific status and may be authorized by different means (Edmond, 2002).

Judicial rulings that declare plaintiffs' evidence inadmissible in class-action lawsuits often result in summary judgments that preclude a jury trial. The rationale for such rulings is that a single judge is more competent to decide the merits of such evidence than is a jury – a collective representative of the lay populace. The question of jury competence or jury understanding has been of concern in the legal domain for at least the past century. Edmond and Mercer (1997) usefully connect that issue to more general debates about the public understanding of science. A predominant viewpoint expressed by Learned Hand (1901) has it that juries are ill-equipped to contend with technical evidence and that panels of independent experts should be entrusted to advise juries

about relevant technical facts, so that their evaluations of the 'ultimate issue' (guilt, innocence, liability) will be well-informed. One counter-argument to such suggestions is that judgments about technical facts often are intertwined with more ordinary evaluations. A notorious jury verdict provides a case in point. William Thompson, who both participated as a defense lawyer in the notorious double-murder trial of *California v. Orenthal James Simpson* in 1995 and has written extensively about police uses and abuses of DNA evidence in criminal trials, contested a common view of the not-guilty verdict returned by the jury in the face of a massive amount of (seemingly) incriminating DNA evidence. The common view was that the jury either willfully ignored or was incapable of comprehending the technical evidence adduced by the prosecution. After elaborating upon a series of anomalous features of the blood evidence collected and analyzed by the prosecution which, the defense argued, pointed to evidence of tampering and incompetence, Thompson asserted:

> An examination of the competing theories also belies the claim that the DNA evidence was too complex or arcane for the jury to understand. Whether the jury believed or disbelieved the tampering theory, for example, probably had relatively little to do with the jurors' understanding of scientific arcana and a great deal to do with the jurors' assessment of facts that they were uniquely well positioned to assess …. There were a number of scientific issues in the case, but they had little to do with the fundamental science underlying DNA testing or the details of laboratory procedures for typing DNA, and everything to do with the potential for cross-contamination of samples before they reached the DNA laboratories.
> Thompson, 1996: 841

Thompson referred to a series of material indications that blood samples had been mishandled, and possibly created through fraudulent planting of blood on Simpson's car and gloves. The resulting DNA matches and probability estimates of coincidence matches in the relevant population, were thus placed in mundane contexts of police malpractice instead of the murderous actions attributed to Simpson. The basis for such judgments of the significance of technical evidence thus turned on nontechnical attributions of motive and narrative scenarios. Thompson (ibid.) concludes that it "seems fatuous to claim, without further proof, that the jury was confused about the DNA evidence." The jury's basis for judgment involved a variant of what is sometimes called 'lay expertise.'

Lay Expertise

An important general insight from the analysis of the scientific and policy field of risk assessment by STS scholarship, has been the observation that such risk assessments, claimed to be realistic and valid knowledge for governance of risk situations, are invariably based on incomplete knowledge, with relevant knowledge being excluded and scientific ignorance in play, yet denied (Wynne, 1992; Irwin and Wynne, 1996; Proctor and Shiebinger, 2008). Frequently it has been found that accredited risk experts who are given policy authority are unaware of these inadequacies in their own knowledge and unable (or unwilling) to recognize other bodies of salient knowledge, which, had they been included, might have improved the full knowledge-base (see Horremous et al., 2002; EEA, 2013). Since risks are delivered and suffered in diverse real practical situations, such salient knowledge includes not only scientific knowledge but also the specialist knowledge practised by others involved with the technologies and networks concerned. In a major controversy over HIV-AIDS treatment and research on therapeutic drugs in the United States in the 1980s, Stephen Epstein documented how gay community activists and medical practitioners joined forces to make the case for new testing and research standards and regimes, which reflected their real conditions of already being at-risk or infected and so in need of therapies even when these were not proven to be safe by normal standards. The unique practical expertise of HIV/AIDS sufferers was salient to the development of more effective policies and therapies. It was not that such experience and community-based knowledge needed to be in competition with salient medical research expertise but that the latter needed to recognize and respect – and also include – the specialist knowledge of the former, nonscientific experts. In many cases, gay community activists acquired selective medical knowledge that enabled them to more effectively collaborate with medical researchers.

In his study of the responses of the highly specialist, practical-knowledge-based, hill sheep farmers of Cumbria, Northern England, to the scientific expertise invoked to try to manage the radioactive fallout from the 1986 Chernobyl nuclear accident, Wynne (1996) described this practice-based specialist farming and related knowledge-culture as an example of 'lay expertise.' Collins and Evans (2002, 2007) took exception to this term and proposed an elaborate classification of several different types of expertise, including their notion of 'contributory expertise' as distinct from 'interactional expertise,' where contributory expertise could include scientific or practical, experience-based expertise in the form of contributing to technical knowledge of the domain at issue. Interactional expertise in any given domain is a form of competence in the specialist language but not in the specialist practices, of knowledge-development: someone who can 'talk the talk,' as it were, but not 'walk the walk.'

The differences between Wynne's approach to what he called lay expertise of the sheep-farmers who interacted with the radioactivity scientists and Collins and Evans's (2002) partly critical interpretation of his case study, have little to do with how expertise is defined, and more to do with Collins and Evans' assumption that the different knowledge-cultures of the farmers and scientists were both devoted to solving the same issue or problem, and that this is a general state of affairs in such interactions. As ethnographic field-researcher in this case, Wynne disagreed, asserting that the primary meanings given to the issue and thus the problems they saw themselves as managing, were different between farmers and scientists; thus such analytical cross-cultural unification does not make sense as an account of reality as it occurred. This question as to whether experts of different kinds are or should be providing only expertise in answering specific, shared, propositional questions ('Is it safe?' for example) or whether they are also defining the meanings of such situations ('What is the issue in question?') is often an

unstated and subtle one (see Wynne, 2003; also Jasanoff, 2003). Many other examples of expertise based on noncertified but impressively durable experience-based specialist knowledge in diverse domains, abound in the literature.

Interactional versus Contributory Expertise

As alluded to in the foregoing section, Collins and Evans (2007) made a strong point of distinguishing between what they called 'contributory' and 'interactional' expertise. While contributory expertise (as the words suggest) contributes to the salient body of specialist expert knowledge, and so is based in authentic practical and cognitive skills exclusive to that expert collective, interactional expertise is qualitatively different. Thus, while the latter form of expert is capable of communicating in the specialist language with contributory experts and interacting as if one of them, such expertise is not capable of actually contributing to the salient corpus of knowledge, for example by designing, conducting, and analyzing productive experimental tests and publishing findings. For Collins and Evans this was a key distinction. Others found it basically valid in principle but of questionable analytical worth, unless one wanted, as Collins and Evans evidently did, to use such identifications to distinguish between participants in a public issue, to decide who is making statements based in real expertise as opposed to interactional expertise or virtually no expertise at all. This corresponds with the concern that Collins and Evans have also expressed over 'the problem of extension,' where in their view, anyone who participates in a public issue tends to claim, or be allocated, equal expertise with designated experts, thus confusing public debate and decision-making to the point of paralysis. Others have argued that a far more significant problem than such over-extension, if it does occur, is a danger of confusing differences in factual knowledge with different orientations to 'matters of concern' between social groups (Latour, 2004). An exclusive attention to expertise with propositional (or factual) issues to the exclusion of differences of meaning and concern about legitimately political issues, threatens to bring us back to questions of technocracy, as discussed before.

Conclusion

The politics of expertise is by no means a new topic but it has become especially salient in STS. In the literature, there are different views on the problem of expertise. Many in STS, as part of the legacy of constructivism, take a skeptical view of expert claims in favor of more widespread public engagement with (seemingly) technical decisions about public health, safety, security, and environmental matters. Increasingly, STS scholars also recognize the need to discriminate between different domains of expertise and different political uses of both expert claims and skepticism about such claims (Turner, 2001). Debates about expertise in the field continue and are tied in with more widespread public controversies about climate change, genetically modified organisms, and many other public concerns.

Science and The State

Abstract

As a body of knowledge, a host of techniques of investigation, a sociocultural configuration, and an outlook, science was a major factor in the emergence of modernity and the shaping of the modern state. Science and technology constituted a principal resource for the military empowerment of the modern state. In addition, they provided technical instruments, organizational tools, and powerful justifications for the interventions of the modern state in such diverse areas as public health, industry, city planning, agriculture, transportation, and more recently environmental protection. In the course of the nineteenth century, the faith in the capacity of science to objectively describe, explain, and control nature was gradually extended to human affairs as sociology, economics, psychology, and other social sciences appeared to certify scientific accounts of social facts and scientific techniques of intervention. While the natural and the social sciences could thus play an important role in the development and the modes of operation of the modern public bureaucracy, they could at the same time be enlisted in free societies as powerful means of public criticism of the state and its actions. Nevertheless, the increasing role of science and technology in modern military conflicts and economic or industrial competition has undermined the long-standing apolitical status of science and technology. Together with these developments, new challenges to the powers and authority of the modern state posed by the globalization of the economy and mass communications, the transformation of relatively homogeneous into ethnically heterogeneous societies, and the spread of multiculturalism, diminished the capacity of the state to function as an agent of large-scale science-based projects. On the other hand, the increasing role of the market and private agents in the applications of science and technology enhances the responsibilities of the state as a regulator charged with protecting the private citizen and the public against the misuses of sciences and technology and their unintended effects.

Introduction

Since the sixteenth century, the 'scientific revolution' has generated a host of new, intellectual, rhetorical, and institutional strategies for undermining traditional political authorities and constructing alternative ones. Science became a vital resource in the modern attempt to discredit traditional political hierarchies and spiritual transcendental sources of authority in the context of public affairs. By providing new rationales for order compatible with the novel modern commitments to the values of individualism, voluntarism, and egalitarianism, science and technology paradoxically also provided new grounds for novel modern forms of hierarchy and authority committed to the use of knowledge in the reconstruction of society. The widely shared notion that science went along with progress appeared to suggest that knowledge, when applied to public affairs, could in fact depoliticize public discourse and action. This faith produced wide mandates for large-scale social and political engineering and monumental state-sponsored technological projects in both authoritarian and democratic states.

While such ideals and projects were from the very beginning criticized by observers such as Edmund Burke (1729–97), throughout the twentieth century the record of relations between science and politics turned out to be sufficiently mixed to discard earlier hopes. The controversial role of scientists in the production and military deployment of means of mass destruction, the role of scientists in the Nazi experiments on human beings and the endorsement of racism, and their involvement in the industrial pollution of the environment, diminished the public trust in science fostered by such developments as medical breakthroughs and spectacular space flights.

Since the closing decades of the twentieth century, an increasing number of social scientists and historians have been pointing out that new uncertainties in the sphere of politics have been converging with newly recognized uncertainties of science and risks of technology to form novel postmodern configurations of state, science, and society (Eisenstadt, 1999; Beck, 1992). It has become increasingly recognized that, in ethnically and religiously heterogeneous and multicultural societies, science and technology can no longer be attached to uncontroversial comprehensive values that privilege claims of neutrality, objectivity, and rationality; nor can the earlier belief that knowledge can depoliticize public discourse and action be sustained any longer.

The Authorities of Science and The State

The belief that science can provide a secular version of the synoptic divine view of human affairs was politically most significant. Until its erosion toward the end of the twentieth century, the modernist configuration of science and the state was formed over the course of at least four centuries. The secularization of political power in the modern state has put the dilemma of arbitrary rule at the center of modern political theory and practice. Whereas legal and constitutional constraints appeared to be the most appropriate remedy to this problem, the rise of modern science and technology encouraged faith in the possibility of restraint and moderation through public enlightenment and by means of scientific and technical advice. Not surprisingly, the redemptive drive behind the integration of science and politics had its origins in premodern religious visions and values (Manuel, 1974).

 http://dx.doi.org/10.1016/B978-0-08-097086-8.85051-5

In both its authoritarian and democratic versions, this modernist program rested on the belief that the modern state can remedy the defects of the present sociopolitical order and realize an ideal order. Science contributed to this modernist outlook a faith in the power of secular knowledge to control nature and reconstruct society. In his dedication to Lorenzo di Medici of Florence in The Prince (1964[1513]), Niccolo Machiavelli implies that the holder of the God's eye view of the entire state is neither the King, who looks down at the people from the top of the hierarchy, nor the people, who see the King at the top from their lower state. It is a person like himself, a man of knowledge. The King, to be sure, has knowledge of the people, and the people have knowledge of the King, but, because of his intellectual perspective, 'a man of humble and obscure condition' like Machiavelli can claim to see both the King and his subjects and understand the nature of their interactions.

Political theory and political science thus claimed to have inherited the God's eye view of the whole polity and evolved a secular vision of the state as an object of knowledge. In turn, the nation-state has often found it useful to adopt the frame, if not always the content, of the inclusive scientific outlook in order to legitimize its interventions in the name of the general common good and its expressions in public goals such as security, health, and economic welfare. If, from the inclusive perspective of the state, all citizens, social groups, or institutions appeared as parts that the supreme power had the capacity to fit together or harmonize, science in its various forms often provided the technical means to rationalize, and the rhetorical strategies to depoliticize, such applications of power.

The potential of science, not only as a source of knowledge but also as a politically useable authority, was already recognized by Thomas Hobbes. This founder of modern political theory was in contact with Francis Bacon, admired William Harvey's findings about the circulation of the blood, and criticized Robert Boyle's position on the vacuum (Shapin and Schaffer, 1985). In his influential works on the state, Hobbes tried to buttress his claims by appealing to the authority of scientific, especially mathematical, certainties, hoping to enlist the special force of a language that claims to generate proofs as distinct from mere opinions (Skinner, 1996). Although he was suspicious of the experimental science of Boyle, Hobbes followed Machiavelli in describing politics in the language of causes rather than motives. Thomas Sprat (1958[1667]), the historian of the Royal Society, claimed that when compared with the contentious languages of religions, the temperate discourse of science could advance consensus across diverse social groups. In both the experimental and mathematical scientific traditions, however, knowledge, whether based on inferences or observations (or on their combination), was expected to end disputes.

The association between science and consensus was regarded as deeply significant in a society that had begun to view authority and order as constructed from the bottom up rather than coming from above (Dumont, 1986). Reinforced by the growing image of science as a cooperative, nonhierarchical, and international enterprise in which free individuals come to uncoerced agreements on the nature of the universe, scientific modes of reasoning and thinking appeared to suggest a model for evolving discipline and order among equals (Polanyi, 1958, 1962).

Deeply compatible with the notion that legitimate power and authority are constituted by social contracts, the rise of modern scientific knowledge appeared to accompany and reinforce the rise of the modern individual and his or her ability to challenge hierarchical forms of knowledge and politics. From Hobbes and Descartes, through Kant, J.S. Mill, and late-modern democratic thinkers such as Popper, Dewey, and Habermas, the commitment to the centrality of individual agency becomes inseparable from a growing faith in the possibility of expanding public enlightenment backed up by the demonstrated success of scientific modes of reasoning and acting.

Power and the Social Sciences

In succeeding centuries, one of the most persistent ambitions of Western society has been to make conclusions touching the 'things' of society, law, and politics appear as compelling and impervious to the fluctuations of mere opinion as conclusions touching the operation of heaven and earth. The faith that natural scientists are bound by the 'plain' language of numbers to speak with an authority that cannot be corrupted by fragile human judgment was gradually extended to the fields of engineering and the social sciences (Porter, 1986). The notion that experts who are disciplined by respect for objective facts are a symbol of integrity and can therefore serve as guardians of public virtues against the villains of politics and business was widely interpreted to include, beyond natural scientists, other categories of experts who speak the language of numbers. Social science disciplines like economics, social statistics, sociology, political science, and psychology adopted modes of observing, inferring, and arguing which appeared to deploy in the sphere of social experience notions of objective facts and discernible laws similar to those that the natural sciences had developed in relation to physical nature. The social sciences discovered that the language of quantification is not only a powerful tool in the production of knowledge of society but also a valuable political and bureaucratic resource for depersonalizing, and thus legitimizing, the exercise of power (Porter, 1995). In the context of social and political life the separation, facilitated by expert languages, between facts and values, causal chains and motives, appeared profoundly consequential. Until effectively challenged, mostly since the 1960s, such scientific and technical orientations to human affairs appeared to produce the belief that economic, social, political, and even moral 'facts' can be used to distinguish subjective or partisan from professional and apolitical arguments or actions. The apparent authority of science in the social and political context motivated the principal founders of modern ideologies like socialism, fascism, and liberalism to enlist science to their views of history, society, and the future.

While theoretical and mathematized scientific knowledge remained esoteric, as religious knowledge had been for centuries in the premodern state, the ethos of general enlightenment and the conception of scientific knowledge as essentially publicly made scientific claims appear agreeable to democratic publics even when those claims remained, in fact, elusive and

removed from their understanding. In fields such as physics, chemistry, and medicine, machines, instruments, and drugs could often validate, in the eyes of the lay public, knowledge claims that theories alone could not substantiate. The belief that science depoliticizes the grounds of state policies and actions, and subordinates them to objective and, at least in the eyes of some, transparent, professional standards, has been highly consequential for the uses of science in the modern state.

Political leaders and public servants discovered that the appearance of transparency and objectivity could make even centralized political power seem publicly accountable (Price, 1965; Ezrahi, 1990). Moreover, the realization that the authority of science could in various contexts be detached from substantive scientific knowledge and deployed without the latter's constraint often enhanced the political usefulness of both natural and social scientists, independently of the value actually accorded to their professional judgments. Still, the uses of expert scientific authority in the legitimization of state politics and programs have often empowered scientists to actually exercise influence on the substance of government actions or to effectively criticize such actions from institutional bases outside the government (Jasanoff, 1990). The actual uses of scientific expertise could often be just the consequence of a political demand for expert authority.

Science in Democratic and Authoritarian States

In democratic societies, the integration of scientific authority, and sometimes also of scientific knowledge and technology, into the operations of the modern state encouraged the development of a scientifically informed public criticism of the government. This process was greatly augmented by the rise of the modern mass media and the ability of scientists to call public attention to governmental failures traceable to nonuse or misuse of scientific expertise. The role of scientists in empowering public criticism of the uses of nuclear weapons and nuclear energy (Balough, 1991), in grounding public criticism of the operation of such agencies as the National Aeronautics and Space Administration (NASA) and the Food and Drug Administration (FDA), and in the criticism of public and private agencies for polluting the environment, illustrates the point. In authoritarian states like the Soviet Union, such cooperation between scientists, the mass media, and the public in criticizing government policies and actually holding the government accountable was, of course, usually repressed. In the authoritarian modernist version of science and the state, science was used mostly to justify, and partly to direct, comprehensive planning and control. Here, the force of scientific knowledge and authority rarely constrained the rationalization of centralization or warranted public skepticism toward the government or criticism of its actions (Scott, 1998).

Even in democratic states, however, science and technology were massively used to promote the goals of reconstruction, coordination, mass production, and uniformity. The redemptive role assumed by the political leadership in the name of equality, public welfare, and uniformity was no less effective in rationalizing state interventions than the totalistic utopianism enlisted to justify the direction and manipulation of society in authoritarian regimes. In all the variants of the modern state, bodies of expert knowledge such as statistics, demography, geography, macroeconomics, city planning, public medicine, mental health, applied physics, psychology, geology, and others were used to rationalize the creation of government organizations and semipublic regulatory bodies which had the mandate to shift at least part of the discretion held formerly by political, legal, and bureaucratic agents to experts (Price, 1965; Wagner et al., 1991).

In many democratic states, the receptiveness to experts within the state bureaucracy was manifest in the introduction of merit-based, selective, personnel recruitment procedures and a widening use of examinations. By contrast, the cases of the former USSR and Communist China suggest the ease with which experts and their expertise could be controlled by political loyalists. Even where it was facilitated, however, the welding of bureaucrats and professionals was bound to be conflict-ridden. The hierarchical authority structure of bureaucratic organizations has inevitably come to both challenge and be challenged by the more horizontal structure of professional peer controls (Wilson, 1989; Larson, 1977). Nevertheless, the professionalization of fields of public policy and regulation boosted the deployment of more strictly instrumental frames of public action in large areas. The synoptic gazes of power and science could thus converge in supporting such projects as holistic social engineering, city planning, and industrial scientific agriculture (Scott, 1998).

Science, War, and Politics

The most dramatic and consequential collaboration between science and the modern state took place during wars. Such collaboration was usually facilitated by the atmosphere of general mobilization, defining the war effort as the top goal of the nation. In a state of emergency, even democratic states have suspended, or at least limited, the competitive political process. Under such conditions, democracies have temporarily, albeit voluntarily, experienced the usual conditions of the authoritarian state: centralized command and control and a nationally coordinated effort. In the aftermath of such wars, politicians and experts often tried to persist in perpetuating the optimal conditions of their collaboration, regarding the resumption of usual political processes as disruptive of orderly rational procedures. In authoritarian nationalist or socialist states, open competitive politics was repressed as a matter of routine, along with the freedom of scientific research and the liberty of scientists to diffuse their findings and interpret them to students and the public at large (Mosse, 1966). In such countries, the political elite usually faced the dilemma of how to exploit the resources of science for the war effort and for advancing domestic goals without becoming vulnerable to the revolutionary potential of science as the expression of free reason, criticism, and what Robert K. Merton (1973) called "organized skepticism." In the democratic state, the special affinities between the participatory ethos of citizens, free to judge and evaluate their government, and the values of scientific knowledge and criticism did not usually allow the coherences and the clarities of the war period to survive for long, and the relations between science and the state had to readjust to

conditions of open political contests and the tensions between scientific advice to, or scientific criticism of, the state. Limitations imposed by open political contests were mitigated, however, in political cultures that encouraged citizens to evaluate and judge the government with reference to the adequacy of its performance in promoting public goals. The links between instrumental success and political legitimation preserved in such contexts the value of the interplay between expert advice to the government and to its public critics in the dynamic making of public policy and the construction of political authority. Political motives for appealing to the authority of science could of course be compatible with a readiness to ignore knowledge and adequate performance, although it did not need to contradict the willingness to actually use scientific knowledge to improve performance. Discrepancies between the uses of scientific authority and scientific knowledge became widespread, however, because of the growing gaps between the timeframes of science and politics in democratic societies. In fields such as public health, economic development, security, and general welfare, the instrumental effectiveness of policies and programs must usually be measured over a period of years, and sometimes even decades. But the politicians whose status has come to be mediated by the modern mass media need to demonstrate their achievements within a timeframe of months or even days or weeks. In contemporary politics, 1 month is a long time, and the life expectancy of issues on the public agenda is usually much shorter. Such a state of affairs means that political actors often lack the political incentives to invest in the costly resources that are required for instrumental success; investments whose payoffs are likely to appear only during the incumbency of their political successors.

Science and the Transformation of the Modern Democratic State

These conditions have encouraged leaders in democratic states increasingly to replace policy decisions and elaborate programs with grand political gestures (Ezrahi, 1990, 2012). Where instant rewards can be obtained by well-advertised commitment to a particular goal or policy, the political motive to invest in substantive moves to change reality and improve governmental performance over the longer run may easily decline.

Besides the tendency of democratic politics to privilege the present over the future in the allocation of public resources, the position of science in substantiating a long-term instrumental approach to public policy was further destabilized by the fragmentation of the normative mandates of state policies. Roughly since the 1960s, the publics of most Western democracies have become increasingly aware of the inherent constraints on the determination and ordering of values for the purpose of guiding public choices. Besides the influence of ethnic, religious, linguistic, or cultural differences on this process, such developments as the feminist movement reflect even deeper pressures to reorder basic values. Feminist spokespersons demanded, for example, that financial and scientific resources directed to control diseases be redistributed to redress gender discrimination against the treatment of specifically female diseases. In part, the feminist critique has been but one aspect of wider processes of individuation, which, toward the later part of the twentieth century, have increased the diversity of identities, tastes, lifestyles, and patterns of association in modern societies. This new pluralism implied the necessity of continually renegotiating the uses of science and technology in the social context, and locally adapting it to the diverse balances of values and interests in different communities. In the course of the twentieth century, leading scientific voices like J.B.S. Haldane, J.B. Bernal, and Jacques Monod tended to treat almost any resistance to the application of advanced scientific knowledge in human affairs as an 'abuse of science' resulting from irrationalism, ignorance, or prejudice. These and many other scientists failed to anticipate changes in social and political values that complicated the relations of science and politics during the twentieth century, and they also failed to anticipate the constraints imposed by the inherently competitive value environment of science and policy making in all modern states.

The constant, often unpredictable, changes in the value orientations of democratic publics, together with other related developments, have clearly undermined confidence in the earlier separation between facts and values, science and politics, and technological and political structures of action. Such a central element of policy making as risk assessment, for example, which for a long time was regarded as a matter best left to scientists, was gradually understood as actually a hybrid process combining science and policy judgments (Jasanoff, 1990; Beck, 1992). In contemporary society, in which the respective authorities of science and the state are demystified, knowledge has come to be regarded as too complex to directly check power, and power as too diffused to direct or repress the production and diffusion of knowledge.

Historically, one of the most important latent functions of science in the sociocultural construction of the democratic political universe was to warrant the faith in an objective world of publicly certifiable facts that can function as standards for the resolution or assessment of conflicts in opinions. To the extent that scientists and technologists could be regarded as having the authority to state the valid relations between causes and effects, they were believed to be vital to the attribution of responsibility for the desirable or undesirable consequences of public actions. Policies were regarded within this model of science and politics as hypotheses, which were subject to tests of experience before a witnessing public (Ezrahi, 1990). Elements of this conception have corresponded to the modern political experience. Although the public gaze has always been mediated, and to some extent manipulated, by hegemonic elites, publics could usually see when a war effort failed to achieve the stated objectives, when a major technology like a nuclear reactor failed and endangered millions of citizens, or when economic policy succeeded in producing affluence and stability. The expansion of this conception of government responsibility and accountability to regions outside the West even made it possible to redescribe fatal hunger in wide areas in India, for instance, as the consequence of policy rather than natural disaster (Sen, 1981). Still, in large areas, the cultural and normative presuppositions of the neutral public realm, as a shared frame for the nonpartisan or nonideological description and evaluation of reality, have not survived the proliferation of

the modern mass media and the spread of political and cultural pluralism. In contemporary democracies, the pervasive mediating role of largely commercialized electronic communication systems has diminished the power of the state to influence public perceptions of politics and accentuated the weight of emotional and esthetic factors relative to knowledge or information in the representation and construction of political reality. Influenced by diverse specialized and individualized electronic media, the proliferation of partly insulated micro-sociocultural universes within the larger society has generated a corresponding proliferation of incommensurable notions of reality, causality, and factuality.

Transformations of the Institutional Structure and Intellectual Orientations of Science

Changes in the political and institutional environment of science in the modern state have been accompanied by changes in the internal institutional and intellectual life of science itself. In the modern democratic state, the status of science as a distinct source of certified knowledge and authority was related to its institutional autonomy vis-à-vis the structure of the state and its independence from private economic institutions. Freedom of research and academic freedom were regarded as necessary conditions for the production and diffusion of scientific knowledge and, therefore, also for its powers to ground apolitical advice and criticism in the context of public affairs. Such institutional autonomy was, of course, never complete. The very conditions of independence and freedom had to be negotiated in each society and reflected at least a tacit balance between the needs of science and the state as perceived by the government. But the international universalistic ethos of science tended to ignore or underplay such local variations (Solingen, 1994).

The institutional arrangements that secured a degree of autonomy and freedom to scientists seemed to warrant the distinction between basic and applied research, between pure research directed to the advancement of knowledge and research and development directed to advancing specific industrial, medical, or other practical goals. An important function of this distinction was to balance the adaptation of science to the needs of the modern state and the preservation of the internal intellectual traditions and practices of scientific research and academic institutions. In practice, the relations between science and the state were more symbiotic than the public ethos of science would have suggested. Scientific institutions, in order to function, almost always required public and political support and often also financial assistance. On the other hand, the state could not remain indifferent to the potential uses of scientific knowledge and authority to both secure adequate responses to problems and facilitate the legitimation of its actions by reference to apolitical expert authority. Thus, while the separation between truth and power and the respect for the boundaries between pure and applied sciences, as well as between politics and administration, were considered for a long time as the appropriate way to think about the relation between science and politics (Price, 1965), the relations between science and the state, as well as between scientists and politicians, turned out to be much more interactive and conflict-ridden. Since scientists and politicians respectively controlled assets useful for each other's work, they were bound to be more active in trying to pressure each other to cooperate and engage in mutually useful exchanges (Gibbons et al., 1994).

Not all these exchanges were useful in the long run, either to science or the state. The mobilization of scientists to assist the war efforts of the modern nation-state, while it boosted the status of scientists domestically in the short run, had deleterious effects on the international network of scientific cooperation, as well as on the independence of science in the long run. Especially in cases of internally controversial wars, such as the American involvement in Vietnam, the mobilization of science inevitably split the scientific community and politicized the status of science. Nevertheless, the unprecedented outlays of public money made available to science in the name of national defense allowed many research institutions to acquire expansive advanced facilities and instruments that permitted the boosting of pure science in addition to militarily related research and development. But the gains in size and in potential scientific advance were obtained at the cost of eroding the glorious insulation of scientific research and exposing its delicate internal navigational mechanisms to the impact of external political values and institutions (Leslie, 1993). Yielding to the pressures of the modern nation-state to make science more relevant and useful to more immediate social goals inevitably reduced the influence of internal scientific considerations and the priorities of scientific research (Guston, 2000). Following such developments, the university, the laboratory, and the scientific community at large could often appear less elitist and more patriotic, but also more detached from their earlier affinities to humanistic culture and liberal values.

Like the partnership between science and the state, the partnership between science and the market, often facilitated by their collaboration during the war effort and postwar privatization of projects and services, has undermined the autonomy of science and the ethos of basic research in many late-modern states. But, whereas the interpenetration between science and the state subjected the internal intellectual values of science to the pressures of public goals and pressing political needs, the links between science and the private sector subordinated scientific norms to the private values of profit making. The conversion of scientific expertise into capital opened the way for substantial private support for the intellectual pursuits of the sciences. But the linkages between science, industry, and capital only reinforced the decline of science and its institutions as a bastion of enlightenment culture, progress, and universal intellectual values. Thus, while scientific and technical knowledge and skills were increasingly integrated into a wider spectrum of industrial productions and commercial services, science as a whole became more amorphous, less recognizable or representable as a set of distinct institutions, and a community with a shared ethos (Gibbons et al., 1994).

An instructive illustration of these processes is the pressure exerted by both the state and private business firms on scientists to compromise the cherished professional norm of publicity (making findings publicly available). In the context of science, the transparency of methodology and the publicity of research results have for a long time been reinforced by both

ethical commitment and practical needs. The methodologies and findings of any research effort are the building blocks, the raw materials, with which scientists in discrete places produce more knowledge. Transparency and publicity are necessary for the orderly flow of the research process and the operation of science as a cooperative enterprise (Merton, 1973). In addition, publicity has been a necessary element of the special status of science as public knowledge. From the very beginning, pioneering scientists such as Bacon, Boyle, and Lavoisier distinguished scientific claims from the claims of magic, alchemy, cabala, and other esoteric practices by the commitment to transparency. Transparency also was what rendered claims of scientific knowledge to appear publicly acceptable by democratic citizens (Tocqueville, 1945). Turning scientific research into a state secret in order to gain an advantage in war or into an economic (commercial) secret in order to gain an advantage in the market was not congenial to sustaining the cooperative system of science or the early luster of science as an embodiment of noble knowledge and virtues which transcended national loyalties and sectoral interests. In the aftermath of such developments, the virtues of objectivity, disinterestedness, universality, and rationality which were associated with earlier configurations of science (Polanyi, 1958, 1962; Merton, 1973) appeared unsustainable. Moreover, the fact that the resources of science and technology could be enlisted, not only by liberal and democratic but also by fascist, communist, and other authoritarian regimes, accentuated the image of science as an instrument insufficiently constrained by internal norms and flexible enough to serve contradictory, unprogressive, and extremely controversial causes.

The Postmodern Condition and the Reconfiguration of Science and The State

These developments had a profoundly paradoxical impact on the status of science in the late-modern state. Especially since the closing decades of the twentieth century, the authority of science in society and in the context of public affairs has suffered a sharp decline, even while such projects as the decoding of the human genome and the hunting for the Higgs Boson particle at the Large Hardon Collider in Geneva indicate that scientific knowledge has advanced beyond even the most optimistic predictions. In order to consider this state of affairs as reversible, one needs to believe that the insular autonomy of science can be restored and that the political and economic environments of science can become more congenial for sustaining this condition. Such expectations seem unwarranted. The long-standing assumption that science can be sharply separable from politics, or even that such separation is always desirable, has lost much of its earlier force. The attempts of science to embody the values of neutrality and objectivity in the political context have declined, due to developments not only within science but in politics as well (Ezrahi, 1996; Jasanoff, 2005).

It is important to stress that the apparent decline in the distinct social and political value of scientific authority, and in the perceived autonomy of science, may not necessarily undermine the impact of scientific knowledge on the ways states and governments act. What appears against the past as the decline of scientific authority in the larger social and political context may be redescribed as a reconfiguration and dispersion of the authority of expertise in the postmodern state. The boundaries perceived earlier between science, politics, law, ethics, economy, and the like may reflect an anachronistic ethos of science which no is longer relevant to contemporary, more sophisticated, views of the multiple decentralized interactions between various bodies of knowledge and their sociopolitical environments. Such interactions require finer, more intricate and continual adjustments and readjustments between science and power, and other perspectives on their relations.

In the absence of hegemonic ideological or national frames, the macropolitical sphere of the state divides into a multitude of – often just temporary and amorphous – subgroups, each organized around a particular order of values and interests. In each of these particular universes, scientific knowledge and expertise can occupy a privileged authority as a means to advance shared goals. When these groups clash or compete in the wider political arena, their experts tend to take sides and function as advocates. The state and its regulatory institutions enlist their own experts to back up their particular perspectives. Within this new, more open-ended and dynamic system, science is more explicitly and reflexively integrated into social, economic, and political values. In the context of the new pluralist polity, the authority and knowledge of science may therefore be less distinctly visible and less relevant to the symbolic, ideological, or cultural aspects of politics. At the same time, it is no less present in the organization, management, and the normative constitution of social order.

Several contemporary theorists have attempted to reconceptualize the relations between science and the state in light of new understandings of the diverse modes of generating and diffusing scientific knowledge and novel configurations of science, technology, politics and the economy in the contemporary state. A few scholars have advanced the idea that knowledge and social order are coproduced by complex processes that ensure a degree of compatibility between the character and authority of the knowledge produced, the framing of political power, and modes of government that become legitimate. This approach has been reinforced by studies that demonstrate the ways in which historically embodied variability in the collective imaginaries of legitimate order like monarchy and democracy evolve respectively matching forms of culture and knowledge (Ezrahi, 2012). This theory has been supported by the finding that diverse sociocultural contexts tend to generate variable perspectives on science, its symbolic contextual implications and applications (Gibbons et al., 1994; Jasanoff, 2004).

Another approach led by Bruno Latour and Michel Callon, and inspired by Gabriel Tarde, Gilles Deleuze, Donna Haraway, and other theorists of interaction and hybrid agents, has aimed at replacing the hegemonic metaphysical dichotomy of subjects and objects with an alternative theory according to which the boundaries between human and nonhuman agents, which they regard as equivalent semiotic "actants," are blurred or canceled (Latour, 2005). The material-semiotic perspective they advance focuses on an imaginary consisting of networks in which human and nonhuman agents (including microbes, inanimate matter, machines, etc.) form dynamic assemblages that generate social actions and processes which compose the social-material whole. This approach challenges conventional

hierarchies composed of persons, objects, and animals by reframing our understanding of the place of science and technology in our social and political world-making.

Whereas the above theories seem to open new ways to understand the relations between science and the state, they also elicit some instructive criticisms. The theory of the coproduction of knowledge and the social order may underestimate the unpredictability and the accelerated revolutionary potential of the advancement of knowledge to undermine established norms and institutions without evolving new ones, and the actor-network theory (ANT) has difficulties dealing with politics and political power and with its problematic diminishment of voluntarism, ethics, and responsibility as central components of social-scientific accounts of the human dimensions of society and politics.

Science Communication

Abstract

Science communication is the communication of scientific knowledge and ideas to people who are not scientists. Communication among scientists is fundamental to the generation and affirmation of scientific knowledge; communication with people who are not scientists serves both to inform them and to identify scientists as a particular form of authority. The products of science communication, which are known as popular science, have distinctive rhetorical features, but are also subject to the trends and values of areas such as journalism and public relations. Theories of science communication have evolved from simple transmission models to ideas more congruent with ideas about the 'network society.' Science communication is used to encourage development in emerging economies, and in post-industrial societies it becomes part of the immaterial production of technological futures, bringing innovations into social life.

'Science' has many meanings. It is a form of enquiry: for some, this includes, very broadly, any systematic enquiry that involves gathering data, developing hypotheses, and testing them; and for others, and also colloquially in the English-speaking world, science means data and hypotheses about the natural world in particular, rather than the social or the metaphysical. Science is also a profession, the members of which are scientists; but in common parlance scientists as a group are usually referred to not as a profession but as a community. Unusually among professions, there is also a common word for people who are not members of this community: they are nonscientists. It is characteristic of science that it is concerned with this kind of classifying, both in its approach to problem-solving and in its assertions of its own identity, from which it draws authority to speak on some topics but absolves itself from responsibility for others. This concern among scientists themselves with demarcating science and scientists from other forms of enquiry, other problems, and other people is reflected in the fact that the communication of science with nonscientists has its own name: science communication. The products of science communication are often called 'popular science,' to distinguish them from communications between scientists.

Communication in Science

The essential role of communication in the formation of modern science is clear in the principles and practices of its founders, who came together and developed a common identity in the seventeenth century in the capitals of Western Europe (Shapin and Schaffer, 1985). The philosophy of empiricism quickly came to dominate: that is, that nature should be encountered not through the imagination or through acts of mental logic, but through direct observation and manipulation of the stuff of the natural world. These experiments would, if competently conducted, yield the same insights wherever, and by whomsoever, they were performed. It was therefore necessary that the experiments should be witnessed, reported in detail, and scrutinized by others, so that the outcomes could be understood collectively. This collective aspect of science was advocated not only as a means to truth about nature but also as having greater social value than the potentially destructive alternative of disputatious factions.

Early scientists sought to extend their community by disseminating accounts of their activities in print: scientific societies published journals that included reports of meetings, scripts of lectures, and also accounts of experiments, to allow distant readers to share in the experience. In Europe, Latin was routinely used to share scientific knowledge abroad, and, later, foreign languages became an important part of a scientist's toolkit. The social transition that resulted in the institution of modern science therefore has communication at its core.

This communication among scientists is considered a normal part of scientific work and fundamental to the social identity and epistemological integrity of science. Communicating with nonscientists, however, has often been considered by scientists as a peripheral and low-status activity. However, these evaluations have varied historically and from place to place and have recently been problematized in science communication studies.

The Origins of Popular Science

While the emerging scientific community sought ways to identify and gather its members, exponents of natural knowledge were also active contributors to the cultural turn known as the Enlightenment. In this preprofessional era for science, writing and speaking about the natural world were among the few ways in which scientists could earn money from it, and the burgeoning public sphere, new media, and new forms of commerce provided new spaces in which to do so. The idea of natural knowledge as a universal good fueled a rich and diverse scene.

The label 'science' is an anachronism at this point and does not imply the strict categorization of later centuries, of authors, subject matter, genre, style, or audience. The literature we would now identify as science was then enmeshed in the general discourse of politics, religion, and society. The proliferation of publishers, media, and readerships brought with it a wide diversity of styles and genres, and, as it framed itself for these new cultural niches, the identity of science was

problematic: one of the most prolific 'science communicators' of the eighteenth century, Buffon, author of the monumental *Natural History*, was embroiled in grave discussions with peers on the relationship between literary style and the facts of nature, including topics such as the extent to which natural knowledge can be conveyed by metaphor. The recurring question was how one can faithfully report the single voice of universal nature, while at the same time meeting the diverse demands of the broader, and ever broadening, popular culture.

The emphasis on consensus as the goal of scientific enquiry, and the wide geographical spread of correspondents and journal readers, made scientists ideal ambassadors. In times of international conflict and expanding empires, scientists were often in the colonial vanguard: ostensibly above politics, they traveled freely, spreading universal knowledge and identifying natural resources to send to the imperial center.

By the nineteenth century, science across Europe was organizing as a profession and seeking an institutional infrastructure and funding. The application of natural knowledge was marketed as the agent of progress, and from industrialization could come wealth. The label 'scientist' was adopted, identifying a new profession. One of the services offered by the new profession in the industrializing countries of Europe was to prepare a workforce for industrial labor and to support the urbanized life that industry entailed. Programs of lectures were orientated around particular industries such as mining or metal-working and on topics such as technical drawing and mechanics.

To gain the authority to advise and the social mandate to practice, scientists identified their knowledge as special and themselves as specialists. This involved displays of the power represented by the communication of their special knowledge to nonscientists, who included both social authorities and the common people. When a monarch undertakes publicity with displays of regalia, the material of power returns to the palace at the end of the tour; knowledge, however, is a nonrival good: the lecturer still has it, but the audience also take it home with them. Fears about the revolutionary potential of evolving democracies and their newly literate citizens focused the attention of the educated elites on the question of how to enable the people for this changing world but at the same time contain any ambition or potential to disrupt the social status quo. Popular science, they argued, risked empowering the masses, but its proper handling could confer discipline, reason, and compliance.

So while public communication of science has often been explicitly committed to Enlightenment ideals, it has usually also happened in the contexts of programs to manage and direct public responses to a changing world more generally and to science and technology in particular. By the end of the nineteenth century in Europe, there was a publishing industry, lecture series, and forms of education about science, directed by scientists and nonscientists. Science communication for nonscientists became distinct from science communication among professionals, which became increasingly esoteric in expensive journals. Scientific journals have been a lucrative and persistent medium: their number has grown by factor of 10 every 50 years since 1650, and they remain a significant medium in the internet era. Journals select for publication only the most significant submissions, so that journal publications are considered the 'gold standard' in scientific productivity and achievement, and are used as a measure of scientists' performance, both by policymakers looking to distribute resources and by academic analysts looking to map the structure and workings of the scientific community.

Charles Darwin (1809–82) is sometimes identified as the last of the amateurs who dominated science before it professionalized, and his theory of evolution by natural selection, published in 1859, is identified as the last significant event in the history of science to be communicated to both scientists and laypeople in one and the same language and form: in the book *On the Origin of Species*. Thereafter, a scientist was someone who worked in science for a salary, and if they wrote for the public, it was in a different forum, medium, and style from their communication with their colleagues.

Science Communication as Popular Science

By the turn of the twentieth century, there were clear, formal routes, controlled by scientific institutions, into science as a profession, and an established market for popular science alongside the flourishing professional science market. Science communicators who were not themselves scientists drew on the long tradition of public talk about natural knowledge and wrote books and magazine articles and embraced new media including film and radio. In Europe, the sudden expansion of the mass market newspaper industry came just in time not only for the highly technological World War I but also for the scientific revolution of the 'new physics,' when relativity theory and quantum mechanics challenged even the best scientists and most proficient communicators. The culturally widespread idea that science is very complicated (and scientists very clever) may have arisen at this time, underlining the value of the specialist practitioners of science communication (Bucchi, 2004).

Science communication has a clear rhetorical identity by this time. Where scientists are understood to be very clever, nonscientists are rhetorically constructed as less so. Science communication often makes explicit assertions about what it assumes its audience does not know or misunderstands: phrases such as 'Many people mistakenly believe that …' will commonly precede a startling revelation of scientific knowledge, often identified as startling by an exclamation mark. Where scientists tend to express their professional claims in tentative, conservative, and incremental terms, science communication deploys a rhetoric of achievement and change, often with confident portrayals of the future. Science communication has traditionally privileged the visual, deploying the evidence of the senses, in the same way as professional science privileges the mathematical, calling on the capacities of intellect and education. Science communication uses literary devices such as narrative, metaphor, and anthropomorphism in contrast to the largely forensic language of professional communication.

These rhetorical conventions are symptoms of the long-standing tension in science communication about how to exhibit knowledge that is esoteric enough to affirm the special status of scientists, while at the same time revealing the value of science that earns it esteem, public support, and, eventually,

taxpayers' money. This tension is also reflected in the classic popular science scenario in which social boundaries are maintained while knowledge is displayed. Difference and distance between the scientist and the nonscientist can be emphasized by the architecture of the lecture hall (often with the physical barrier of the lab bench between lecturer and audience), styles of dress (the white coat), or linguistic conventions (such as jargon). This holds the public at arm's length so as to emphasize difference but at the same time benefit from the affirmation provided by their proximity (Gieryn, 1999).

Science communication has many purposes for scientists, not least of which is the need to secure funding and other resources such as positive public opinion (Dornan, 1990). It tends to flourish in times of crisis in the political fortunes of science. It is also a way for scientists to reach each other via the public sphere, untrammelled by the selectivity and strict conventions of journal publications, and so scientists use science communication to fight their corner both in the early days of new fields and when their status is receding. A confident, well-resourced, and productive discipline or field is usually quieter in the public sphere.

Science communication typically claims the political neutrality often attributed to scientists and does not ask its audience to behave in particular ways: it is enlightening, rather than educational. Unlike education, popular science can be merely surprising; it does not have to be meaningful or comprehensible. This distinction between education and enlightenment is strict enough to have produced explicitly hybrid institutions, such as science centers, which deploy the techniques of science communication in an explicitly educational setting, and are often linked to national educational programs.

Jurdant (1993) characterizes science communication as the autobiography of science: it is the story science tells about itself. It is idealized and tidied up and excused from the contingencies of practice. It tends to retrospectively construct direct paths from experiment to discovery, when scientists may instead talk among themselves about difficulties, diversions, and set-backs; it focuses on the emerging consensus rather than controversy from which it emerged. Its neutrality is presented as objectivity. Latour (1987) characterizes this as the 'Janus face' of science, contrasting the relatively private 'inward' talk among scientists with the 'outward' public stories being told to nonscientists.

Science Communication as Politics

Professional science journalists established a recognized beat in the West during the 1930s, and science and politics came together on the global platform of World War II, most visibly in response to the atomic bomb, which established a form of journalism, delivered by specialist reporters, that was enthusiastic about the technical wizardry of science and committed to its role in shaping the post-war reconstruction. The economic and social dimensions of science gave mainstream journalists their entrée into this new beat, and their message was one of faith in scientific rationality and technological progress.

Science was also brought into mainstream politics during the 1960s in the West via restructuring of public funding for science and became an issue of domestic politics. At this time too, science journalists were rediscovering the critical spirit of mainstream journalism. In a society tending toward a critical approach to authority more generally, the public sphere was becoming an increasingly combative space for science, involving new actors and voices from outside the scientific community, such as new social movements focused on issues such as human rights, the environment, health, and war. Scientists became less confident in this pluralized discourse and to a significant extent withdrew from the public sphere, leaving space for challenges to scientific authority and for alternative worldviews. Another reason to turn back toward their own community came in 1969, when the editor of the highly prestigious *New England Journal of Medicine*, Franz Ingelfinger, declared that no research could be published in his journal if it had already been exposed in public. For individual scientists, who needed publications to secure their careers, the choice was clear. The Ingelfinger rule spread quickly among journals and remains a condition of journal publication today – one that journals exploit through their own public relations activity by turning publication, rather than the research itself, into a news event.

The turn away from public communication was problematized during the 1980s by scientists themselves. With the advent of neoliberal economics and pressure on publicly funded scientists to contribute to wealth creation, scientists became conscious of the extent to which their market value depended on public opinion. In an era considered by historians and sociologists to be a turning point in the cultural status of science, and at a time of ambivalence in relation to authorities of all kinds, scientists took a renewed interest in their public relations (Bauer and Bucchi, 2007).

As a consequence, funding was made available for science communication activity of many kinds. This also provided a commercial opportunity for publishers and other media organizations to develop science content, at a time when the global media industry was developing into a multichannel, transnational business. Through the 1990s, scientific institutions became alert to the benefits of media coverage and found ways of collaborating with journalists. Now very few research institutes in Europe are without their press office. The universities work closely with the journals that publish their scientists' research, coordinating press releases and respecting embargoes. Journals publish not only press releases but also news digests to help journalists access their esoteric contents. Thus publication in an esoteric journal can automatically mean exposure in the public sphere for an author who thus brings their work, their institution, and the journal to the attention of opinion leaders, policy-makers, and the public, without ever having to step out of the laboratory. Some observers claim that journals' prestige is now measured, at least in part, by the amount of media coverage they can attract and that media potential may be a factor in journal editors' decisions about whether or not to publish a research paper.

The internet-based journalism that arises from the press releases of high-prestige international journals has come to dominate science reporting. In the United Kingdom, science news is dominated by research press-released from journals, and a story in one newspaper will be repeated in several others, with the same photograph and quotes, often uninflected by the

newspaper's political stance. This uniformity among media outlets that traditionally made a virtue of their political differences is a peculiar feature of science reporting and one that worries some critics, who see a loss of democratic potential in the journalists' close relationships with institutions' press officers. At the same time, with scientific research in the West being undertaken increasingly in private institutions such as businesses, science news is not press-released to protect it from competition; so a proportion of scientific research is already withheld from media scrutiny.

Beyond the mass media, the tendency toward centrist politics set the context for novel approaches to many aspects of social life, including the relations between science and society (Gregory and Lock, 2008). Instead of the adversarial politics of the traditional Left and Right, a consensus-seeking approach to the middle ground deployed consultative and dialogic interaction between the public and policymakers, including in areas of scientific research such as genetically modified food and nanotechnology. This approach made science a matter for negotiation among interest groups, and science communication activity was reorientated toward events that encouraged dialogue. These events were often called 'public engagement with science' to distinguish them from traditional science communication. Although engagement as identified as a way of enhancing democratic interaction, its agenda is nevertheless, like traditional science communication, invariably set by the more powerful actors; and participants may experience a process that echoes the management of the workers in the nineteenth century. Critics of public engagement note that what appears to be an open negotiation may be very closely prescribed, with a restricted range of topics and potential outcomes, and that such events are often staged to provide a moderate alternative to street protests or activist campaigns (Lezuan and Soneryd, 2007). This prescriptive aspect takes engagement toward the principles of professional public relations. This situates engagement within the broader trend in science communication, which increasingly adopts the rhetoric and values of public relations.

Theoretical Models of Science Communication

Research into science communication has tended to focus on the efficiency of the transfer of information and has often been conflated with studies of 'scientific literacy' or 'public understanding of science,' which refer to what nonscientists know about science. This knowledge tends to be described as deficient in quality and quantity in comparison to the knowledge of scientists. In this 'deficit model' of public understanding of science there is a normative element that the deficit should be remedied; and the remedy is to transmit knowledge from scientists to laypeople (Gregory and Miller, 1998). There is often a tacit assumption that increasing the public's knowledge will also lead to more positive attitudes toward science – an assumption that is itself based on the common but often unfounded assumption of widespread negative public attitudes to science. However, research on these questions consistently indicates that greater knowledge does not necessarily generate more positive attitudes; and more science communication does not necessarily result in higher levels of knowledge. Critics have also asked 'why' the public's 'deficit' should be remedied, when their ignorance may be socially functional, and the purpose of scientists is that they should be the ones who know about science. Most people know very little of many areas of knowledge, and societies seem to function nevertheless. The deficit model shows, then, an ideology that is not grounded in empirical evidence.

Much of the criticism of the media coverage of science, and the ambitions for science communication, can be conceptualized using what Hilgartner (1990) identified as the dominant model of science communication. Hilgartner noted that much science communication by scientists is framed by the idea that science is emitted by scientists and transmitted by journalists to a receptive public. In this regard, the model is similar to the sender-transmitter-receiver model of classical communication studies. However, the model also embodies social relations, and the transmission process it expresses is vertical, with the scientists at the top. Scientists have the highest-quality knowledge, which they allow to trickle down to journalists whose job is to pass on the information as faithfully as they can. The final destination of this pristine knowledge is a passive, uncritical public, who listen but do not speak. The classic expression of this model is that science communication is about 'bringing it down to their level.' The position of the journalist as mediator maintains a separation between scientists and the public and allows the journalist to stand as scapegoat for communication failures, such as public misunderstandings or lack of political interest.

Communication scholars argue that the public communication of science does not work in this way. Instead, science communication is a complex network of institutions, ideas, and actors who collectively participate in the production of popular science. The public, journalists, and scientists are active participants from a range of backgrounds and playing multiple roles, interacting in many directions and with a variety of media, picking up, passing on, and inflecting information and comment about science (Lewenstein, 1995). Public engagement is an expression of this more fluid, participatory approach to science communication.

The idea of science communication as a complex network brings it into the mainstream of communication theory, alongside many other areas of communication. By the end of the twentieth century, it was adapting to a world transformed by new technologies; and traditional hierarchical social relations, such as those expressed in the dominant model, were sitting uncomfortably among spontaneous and ever-changing horizontal networks. In these networks, there is no clear divide between who can speak and who must listen, with many playing both parts; and the markers of expertise and authority are often difficult to identify. Science communication in early twenty-first century should therefore be understood in the context of theories about this 'network society.'

Science Communication in the 'Network Society'

According to its leading proponent Castells (2000), the 'network society' is a result of three conditions: first, the social changes wrought by and expressed in the cultural and social

movements of 1960s and 1970s, such as feminism, environmentalism, and the antiwar movements, which brought an unprecedented diversity of issues, opinions, and expertises into the public sphere; second, the turn to digital in information technology in the 1970s and the spread of the personal computer from the mid-1980s; and third, the dominance of neo-liberal economics by the end of century. Networks are a longstanding form of social organization: the innovation in the network society is that the networks process and manage information. Information management is an activity that is characteristic of a post-industrial society, where much of economic production is about immaterial goods such as knowledge and experiences. Science is increasingly organizing its relationships in mediated networks, gradually replacing or complementing social networks of face-to-face communication. For scientists, their primary social group is no longer their immediate neighbors and their national context, but instead the individuals with whom they connect from across the global network of the internet. The internet is an open network, and scientists and nonscientists share access to many of the same tools and knowledge, and information can travel not only in expensive journals but also freely, and instantaneously, through electronic networks, facilitating distributed collaborations and diverse critiques.

Scientists benefit from being in a network by the access it grants them to specific and rare resources, and also from the broader network of collaborators, and the global exchange of free-floating ideas and information that may change the course of research (Wagner, 2009). Researchers are free to join forces to tackle common problems regardless of where they are geographically, and their outputs are accessible to a geographically distributed audience of readers, commentators, and critics. The internet as a medium supports interpersonal communication, organizational/business communication, and mass communication all at the same time, which blurs the boundaries between the traditionally distinct roles and audiences in science communication: nonscientists can easily access scientists' professional communications, and anyone can publish scientific information on the Internet without it being subject to the gate-keeping performed by scientists for their professional journals. Advocates of alternative or 'fringe' sciences readily find a platform there, mobilizing the tools, rhetorics, and audiences of mainstream science. The reach, scale, and spontaneity of the network empower its users, providing scope for insurgent politics, particularly on issues of global concern such as the environment and infectious disease.

Networks also play a part in the acceptance or rejection of innovations in society. In a post-industrial, late-capitalist economy, a competitive nation will secure its place in the global market primarily through the promotion of innovation, and of the social and economic conditions for innovation, and by making ready a public for novel goods. Networks enable a small group of supporters of the innovation to share their enthusiasm not just by the traditional 'word of mouth' in interpersonal networks but also through the instantaneous global networks of the internet where science communication serves to display and elucidate the benefits of new products (Rogers, 2003). Markets quickly become saturated, and producers must adapt, making further innovations that can create new markets.

Networks can also restrain innovation by mobilizing critiques of new products and creating representations of their negative attributes or consequences. Markets are vulnerable to public opinion, and in the network society there is space for many points of view to compete for attention. Studies of responses to new technologies show how complex they are: for example, responses to biotechnology across Europe showed similarities and differences between cultures, nations, and regions that appear to relate variously to the religious context, history, media norms, linguistic resources, values, gender, individual wealth, and degree of industrialization, among other factors (Bauer and Gaskell, 2002). Such data potentially allow science communicators to intervene in attitude formation: they could, for example, attempt to mitigate moral concerns about a new product by emphasizing its usefulness.

Less industrialized countries are often more open to new technologies than their more industrialized neighbors. Science communication is increasingly promoted as a tool for development in less industrialized parts of the world, where, for example, cheap wireless technologies are not only an innovation in themselves but also bring the potential for social innovation, by providing an instant infrastructure for technologically, economically, and politically disenfranchised groups. In these as well as in other ways, science communication becomes a kind of activism, with a diverse membership and across a spectrum of loyalties, and outwith the control of any formal agency. In the network society, the traditional roles and controls no longer apply.

Science Communication as Immaterial Labor

Much of economic production in the post-industrial context involves knowledge and services. Anyone who puts information on the Internet is a producer, and consumers of this information also contribute to producing the network itself, which does not exist until and unless people use it. Thus production and consumption are conflated in a single act. Matters of public good, such as education, healthcare, and knowledge, become commodified. Science communication is readily commodified in such an environment (Thorpe and Gregory, 2010).

Technologies have social meanings, and these meanings are an important aspect of their value, which extends beyond the ostensible purpose of the technology itself. These meanings are constructed and shared through intellectual and affective work that is typical of post-industrial capitalist societies. This work, which can be described as a form of immaterial labor, brings immaterial attributes to the commodity, such as hope, freedom, or a sense of belonging. Developing these attributes means bringing the emotions and communicative capabilites of the worker into the production process, so that the communicative activities we think of as being about enlightenment and the values of the public sphere are brought into the sphere of production. Not only are the workers mobilized in this way, but so too are the consumers of the information they produce: the public is productive in that it confers as sense of reality on innovation – in effect, making it – and accepts it (or not), by bringing it into the social world. While science and

technology have long been represented as contributing goods and services to the economy, now, in the post-industrial world, the public communication of science contributes to the economy too and becomes a good in itself.

Traditional science communication has typically appealed to its readers' reason, and activists who have deployed an emotional discourse have been criticized as unscientific: 'sensationalist' is a common disparagement. But in the post-industrial society, the emotions are mobilized in support of new technologies, and the promises about these technologies are not only about their efficiency for a prescribed task, but also about aesthetics, experiences, and better futures. Hopes and expectations about future applications are essential for attracting venture capital, so the construction and management of expectations becomes integral to scientific development. The practice of 'upstream engagement' contemplates future technologies, which may have little basis in present capabilities or knowledge, but which allow public opinion a preview that minimizes the risk of future market failure. In such cases, there is nothing to the issue but talk: the only commodity is the public talk, which brings the future technology into the present. Here, the boundary is blurred between science communication and science fiction: the imaginings of new technologies are already immaterial products with value in the mass media; there they attract both government interest and private investment. Thus, science communication enrolls participants into the immaterial production of imagined futures, integrating them with social values and turning innovations into everyday objects through public talk.

Conclusion

The plurality of the network society supports science communication in a wide range of forms and media and speaks with multiple voices in a variety of roles. Science communicators work in a variety of roles in museums, businesses, government and universities, as well as media institutions. Science communication is subject both to the changing context for science and to the changing frame of the public sphere: it reflects the turn from unquestioning respect for authority to the challenge of activism; from control over the messages about science in the public sphere to a more open and fluid interaction; the emergence of public relations as a dominating mode of information management; and the shift from industrial to post-industrial production. At the same time, science communication retains its connotations of enlightenment, and is experienced as such, by a variety of audiences in many cultural niches as well as on a global scale.

Science: Constructivist Perspectives, History of

Iwan R Morus, Aberystwyth University, Aberystwyth, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

This article provides a summary of developments in the history of science informed by social constructivist perspectives since the 1970s. It discusses key influential texts and highlights historical themes of particular importance such as the understanding of science as local culture, the material culture of experiment, science and performance, and science and labor. The article also emphasizes the constructivist understanding of science as a species of skilled practice and the ways in which such accounts draw attention to the importance of understanding the circulation of skills in the development and consolidation of new knowledge.

Historians of science inspired by the strong program in the sociology of scientific knowledge have developed new approaches to understand science's past. Rather than considering science as an abstract, disembodied body of ideas they have focused on science as a localized practice, embedded in material, national, and political cultures. They have looked at the work involved in making experimental phenomena robust and repeatable. They have looked at the skills involved: their origins, their translation from site to site and individual to individual, their instrumental embodiment, and the changing social status of their possessors. This has focused attention on the ways in which scientists have represented themselves, the knowledge they produce, and on the ways in which they and their products have been represented. Economic, social, and political interests were at stake in such processes. How knowledge was historically constructed was highly consequential for the organization of society. Such histories have also focused on how audiences have received, actively appropriated, and reformulated science in different contexts. Science, from this perspective, is a constant process of production, reproduction, and consumption.

The last quarter of the twentieth century saw the emergence of a challenging new perspective on the sciences and their history. Drawing on developments in the social studies of science, as well as new trends in labor and social history, historians began to look at science as a local practice, rather than as an abstract, disembodied, and universal set of ideas. Such historians started looking at science as part of culture, locally constituted in particular material, social, and even political practices. Constructivist historians are interested in the detailed processes of scientific knowledge production, dissemination, and reception. They differ from more traditional social historians of science in their insistence that the content as well as the context of science is a proper focus of cultural historical analysis. Constructivist historians see science as a species of skilled practice and therefore inquire into the cultural origins of those skills; the means and the spaces through which they are produced, validated, and disseminated; and the ways in which particular forms of inquiry – and particular kinds of knowledge – have historically been characterized as scientific.

Local Cultures

In their exemplary study of the early modern culture of experiment, Shapin and Schaffer lay out some of the central concerns of the constructivist history of science (Shapin and Schaffer, 2011[1985]). Focusing on the dispute between Robert Boyle and Thomas Hobbes concerning the validity of Boyle's famous air-pump experiments, they use Hobbes' critique of Boyle's experiments to lay bare the interests underlying them and the strategies that Boyle and his allies adopted to convince others of the experiments' reliability. They demonstrate how even such an apparently universal cornerstone of the scientific method as experiment has its origins in particular local and contingent circumstances. Making science local and examining the interests that underlie the articulation and resolution of scientific debates have been the preoccupations of constructivist history. Other pioneering studies include accounts of the ways that disillusionment with rational philosophy and mechanistic notions of causality in postwar Weimar Germany informed interpretations of quantum theory (Forman, 1971), and of the role social interests played in debates concerning the anatomical structure of the brain in the early nineteenth-century Edinburgh (Shapin, 1979). Such studies emphasize that such interests are constitutive rather than contingent features of even the most apparently abstract and technical forms of knowledge.

One important outcome of constructivist history is the recognition that even the issue of what kind of activity might count as science is often the product of locally articulated debates and controversies. Not only did Boyle and Hobbes disagree as to what might reliably be inferred from the outcome of air-pump experiments, but they also disagreed as to whether or not doing such experiments should be counted as a reliable way of generating scientific knowledge at all. Similarly, members of the scientific and the medical establishment who opposed the introduction of continental ideas concerning evolution and transmutation into early Victorian England did so both because they did not recognize the practices or the practitioners involved as being properly scientific and because they disagreed with the theories themselves (Desmond, 1989). As the labels 'science' and 'scientific' gained in cultural value, so too did different groups of knowledge producers disagree more vociferously as to what kinds of people and what kinds of activity should be accorded those labels (Gieryn, 1999). Constructivist historians have identified the business of policing the constantly changing boundaries of science as a crucial part of science's history. Through institutions, regimes of training, control of resources, and access to networks

of patronage, natural philosophers and scientists have struggled to circumscribe and discipline their own and others' knowledge-producing activities.

This localist historical perspective leads to recognition of the extent to which the production and validation of scientific knowledge are contingent upon more or less informal networks of trust. In order for particular groups or individuals to be considered reliable spokespersons for nature, they have to be trustworthy. They have to be the kinds of people who can be relied upon to tell the truth. This opens up the possibility of producing a cultural history of truth and objectivity. The marks of being trustworthy vary depending on time and place. In early modern England, for example, trustworthiness was considered the hallmark of the gentleman (Shapin, 1994). As a result, many of the informal (and more formal) rules of early modern gentlemanly behavior became enshrined as codes of conduct for the nascent scientific community as well. Some historians have argued that the increased scientific reliance on precision measurement and self-registering instrumentation since the beginning of the nineteenth century may be regarded as efforts to circumvent the need for trusting individuals with knowledge production (Schaffer, 1988). Others have pinpointed the increasing quantification of science as a means of overcoming the problem of trust in the production and particularly in the transfer of knowledge (Porter, 1995). The attention to local culture also emphasizes the historical importance of space and spatiality in the production and consumption of scientific knowledge (Livingstone, 2003).

The Material Culture of Experiment

Constructivist history of science pays particular attention to the process of experiment. Experimentation is taken to be a matter of human agents actively engaged in constructing the natural world around them (Gooding et al., 1989). The material culture of experiment is a crucial focus of attention. Historians have worked to recover the kinds of material resources required for successful experimentation. They have traced the emergence of the laboratory as a specialized space within which experiments take place. They have emphasized the ways in which successful manipulation of nature requires the experimenter to manipulate material and social resources successfully (Latour, 1988). Michael Faraday's discovery of electromagnetic induction, for example, involved as much his marshalling of the Royal Institution's considerable resources as it did his artful manipulations of materials in the laboratory (Morus, 1998). Constructivist historians have identified as well the important ways in which individual scientific reputations hinge upon recognition of the property relationship between experiment and experimenter. Priority disputes in science are frequent and virulent precisely because of the ways in which experiments embody the skills and reputations of their makers (Iliffe, 1992).

Seeing experiment as a skilled activity, constructivist historians have focused on understanding the historical origins of the kinds of skills required in order to carry out experiments. They have investigated how particular skills have been transferred into the laboratory from other settings, such as workshops or factories. Historical experiments have been replicated in an effort to better understand the tacit, unarticulated skills required for their successful performance. Such studies have shown how iconic experiments, such as James Prescott Joule's famous paddle-wheel experiments establishing the mechanical equivalent of heat during the 1840s, were contingent upon the technical know-how that Joule and his workers derived from their experiences in the family brewery (Sibum, 1995). Historians have also looked at the politics of skill in the laboratory and elsewhere, investigating the division and distribution of hierarchies of skilled activity within science at different times and places. Much attention has been devoted to the historical transmission of material resources and skilled personnel that accompanies the standardization of experimental practices. Work in this vein has shown how experiments move from being instances of highly skilled, difficult to replicate, and delicate procedures performed in highly circumscribed settings to being robust, standardized, and readily reproducible embodiments of group knowledge (Galison, 1987).

Apparently self-evident features of experimentation, such as precision measurement, are shown by constructivist historians to have a history. Measurement can be taken to be an expression of particular cultural values (Wise, 1995). The rise of metrology, for example, was an expression of science's increasing embeddedness in and contribution to a rapidly bureaucratizing and industrializing Western culture. Measurement could be regarded not only as a means of disciplining nature, rendering it more amenable to standardized routines of inquiry, but also as a means of disciplining the scientific workforce. Nineteenth-century scientific managers, such as George Biddell Airy, the English Astronomer Royal, regarded their laboratories and observatories as industrial workplaces and used regimes of routinized measurement and calculation to impose an industrial discipline on their workforces (Ashworth, 1998). In the late nineteenth-century laboratories at Cambridge or Glasgow, natural philosophers such as James Clerk Maxwell or Lord Kelvin saw in regimes of precision measurement in teaching and research, an expression of their affinity with industrializing society (Schaffer, 1992). Constructivist historians have investigated how adherence to cultural values like precision came to be taken as a hallmark of what it meant to be properly scientific. Such historians have also investigated the relationships between the material cultures of the laboratory and of fieldwork, showing how workers in the field, such as twentieth-century primatologists, have developed their own distinctive material and methodological cultures and disciplines (Rees, 2009). Constructivist historians have interrogated theory, using the analytical tools developed to understand experiment to look at theory as a form of cultural practice as well. From this perspective, processes of theory construction and dissemination are seen in terms of the pedagogical training and practical skills required to participate in highly specialized theoretical cultures (Warwick, 2003).

Science as Performance

One notable outcome of constructivist historical work has been to make the identity of the scientific practitioner itself problematic. Being a scientist is not a self-evident activity: the

word itself is of comparatively recent, early nineteenth-century origin. Scientific practitioners in the past occupied a number of different cultural niches. Constructivist historians have shown how natural philosophers at different times and places have been engaged actively in carving out social spaces for themselves and their work. Galileo's position at the Medici court in Renaissance Florence, for example, was not ready-made. Galileo had to work hard to promote the idea of a philosopher or mathematician courtier that he could then fulfill (Biagioli, 1993). He had to fashion himself into the kind of person who could easily inhabit that cultural niche and then to orient his work so that it would fit into the milieu of Italian Renaissance court life. The same could be said of Humphry Davy and his efforts to forge a place for the fashionable natural philosopher in Georgian London (Golinski, 1992). Constructivist approaches share with the 'new history' an emphasis on the important role of individual agents' artful engagement in constructing both themselves and their worlds.

Recent work has paid particular attention to the body of the scientific practitioner (Lawrence and Shapin, 1998). This is an outgrowth of the insistence on viewing scientific practices and the knowledge they produce as being embodied. Scientific practitioners at different times and places have needed to be particular kinds of human beings with specific bodily attributes. The ways in which those attributes were held to be best produced – whether by birth, self-discipline, or rigorous training – have been a focus of increasing historical attention. Historians have examined, for example, the relationship between bodily, mental, and moral discipline in Victorian electrical metrology (Gooday, 2004). The bodily interaction of practitioners with their experimental apparatus and the spatial organization of their laboratories have come to be recognized as playing an important role in the production of knowledge. The organization of such spaces and the kinds of material interactions between practitioners, and between them and their instruments, that have been taken to produce reliable knowledge are now seen as contingent and open to historical investigation.

Not only the identity and activities of the practitioner producing knowledge, but also the role of the audience for such productions is now recognized as constitutive. Audiences for scientific knowledge do not simply act as passive receivers of settled and unproblematic matters of fact. They have an important and active role to play in the articulation and resolution of controversies. During the early modern period and well into the nineteenth century, experiments were often performed before an audience. This was not simply a matter of demonstration. Members of the audience – prestigious and often named individually – played an important role in validating the knowledge produced. Their reputations could be used to underwrite the matters of fact they had witnessed. Audiences have participated in and responded to the processes of knowledge production through a variety of media, from direct witnessing to the virtual witnessing of reading a scientific paper at first hand, to the reception of second- or third-hand reports in museums, newspapers, reviews, or popular handbooks. Public scientific performances are therefore an important part of the dynamic process of knowledge production and validation. This draws attention to the visual culture of science too, and the historical construction of seeing as the paradigm of knowing (Morus, 2006).

Science at Work

This kind of history also looks at the many ways in which nature has been used historically as a model for social organization. The constitution of the natural economy has frequently been used as a powerful argument in favor of particular ways of ordering society (Roberts et al., 2008). Natural theology in the late eighteenth and early nineteenth centuries, for example, was widely used as an argument in favor of existing social hierarchies. Evolutionary theories were similarly cited to support new, meritocratic visions of society. The proper social economy was often held to mirror the natural order. Constructivist historians have shown how models of nature and society in the past were frequently mutually sustaining. They were produced together. Discussions in mid-nineteenth-century thermodynamics surrounding issues of work and waste in natural economies were coextensive with arguments concerning the proper organization of work and the minimization of waste in political economy (Smith and Wise, 1989). Proponents of new forms of industrial organization looked to nature for their models, while scientists looked to factory organization as a model for the best means of ordering the search for truth.

Different models for the organization of scientific work often expressed different understandings not only of how nature was ordered but also of the proper politics of knowledge production. Nineteenth-century scientific gentlemen, for example, regarded scientific work as a highly disciplined, hierarchical, and increasingly specialized activity. In principle, it was open to all. In practice, however, it could only be conducted properly either by, or under the supervision of, properly trained and vocationally committed 'gentlemen of science' (Rudwick, 1985). Other social groups had different notions of the politics of knowledge. The gentlemen's vision excluded women and artisans, for example, from anything other than a supportive role in making knowledge. Working-class men, on the other hand, could construct their own very different accounts of how knowledge making ought to be organized (Secord, 1994).

Through constructivist historical analysis, many of the traditional analytical categories employed by historians and sociologists of science have become recognized as being themselves in need of careful historical contextualization. Pronouncements by historical actors concerning matters such as the scientific method, experimentation, objectivity, or even more novel analytical categories, such as skill, are not to be taken at face value. Such pronouncements usually carry considerable freight. Deciding what kind of activity might properly be considered as an experiment, for example, is not straightforward. At different times, experimentation has been regarded as both a public and a private process. It has been characterized as both a fundamentally communal and an essentially individual activity. Again, what it means to be a skilled worker has changed a great deal since the early modern period. Skill, like method, or even science itself, is a historical construction. By looking at science as a preeminent cultural activity, constructivist histories of science have made it possible

to raise a whole host of new questions concerning the ways in which human beings, in the past, have tried to make sense of the world around them. Rather than seeing science as a static, monolithic edifice, constructivist history recognizes it as a constantly changing process of production, reproduction, and consumption; its boundaries continually shifting and its meaning always open to renegotiation.

Abstract

The evolution of formal school science education, in response to changing attitudes toward science, is summarized. The content and structure of the curriculum, including the relationships to technological applications and to the nature of science, are presented. Assumptions about learning, assessment, and science teacher education are given. The evolution, the nature and provision, of informal science education is summarized. The nature and use of research into both formal and informal science education are briefly discussed.

Science education refers to the teaching and learning of the ideas produced by the sciences, to the ways in which these are produced, ratified, and accepted, by the community of scientists, and to the implications of the uses to which this knowledge are or could be put. It is provided both formally, that is within a framework of a prescribed curriculum and a specialized institution (the school), and informally, that is extracurricularly and in a variety of physical situations. The development of formal science education has been one of the most significant events in school education over the last 170 years, whilst informal provision has only recently come into prominence. Some features of both can be illustrated largely with respect to England.

The Provision of Formal Science Education

The Development of the Provision of Formal Science Education

The early inclusion of science education as an option in the curriculum of some schools took place in the mid-nineteenth century in Western Europe and North America. For example, in England, the subject was being taught in some fee-paying private secondary (high) schools in the 1850s, perhaps in recognition of the growing importance of science in industrial production (Layton, 1973). By 1870, there was discussion at national level about what should be included in the science curriculum and efforts were begun to systematically train science teachers. From then on, the provision of science education expanded progressively but unevenly until it included all primary (elementary) and secondary (high) schools and all pupils, together with the systematic training and certification of science teachers (Jenkins, 1979). The increased involvement of the state led to a national school science curriculum becoming mandatory in 1988, during the subsequent evolution of which the influence of the academic science and science education communities decreased considerably (Fensham, 2013). This sequence of events has been approximately replicated throughout the world, albeit to different degrees and at different speeds.

The Evolution of Formal Science Education

Changing Purposes

At its inception, there was tension with respect to the aims of school science education. Was it to provide 'citizen science,' that is an education that would deal with the contribution of science to the everyday personal, social, economic, and cultural concerns of the general public? Or was it to provide 'prevocational' science, a basic knowledge of the most important facts, concepts, and processes of science as a preparation for students to go on to advanced study of a science at university or technical institute? The prevocational emphasis came to dominate the debate, but was continuously questioned for a number of reasons. First, as the provision of science education expanded and became compulsory to below the minimum school-leaving age, an ever-lower proportion of students in a given school class were interested in higher education in a science. Second, the rapid expansion of output from scientific research meant that the prevocational school science curriculum gradually became overloaded with content, such that students were introduced to isolated facts and concepts, being increasingly unable to see the relation between them and their significance. Third, the growing impact of science on the everyday lives of students meant that the traditional presentation of ideas as largely devoid of their applications and implications become ever less interesting to many students. Fourth, the pedagogy most commonly adopted was based on the assumption that the duty of the teacher was to present information in an efficient manner and that of the students was to memorize a mental 'copy' of it that was to be reproduced in examinations. This approach proved unsuccessful, in that only a small proportion of students were ever successful in fully meeting its demands. Taken together, these factors led to many students developing negative attitudes not only to science education, which meant that they did not continue to study it when given the option not to, but also to science itself, which was a matter of concern for the community of scientists and industrialists.

Attitudes to Science

Attitudes toward science and science education in schools are manifest in the active engagement of students in science lessons and in their interest in seeking a career in science or technology. Enquiries into such attitudes have shown them to be influenced by many factors, including their personal responses to classroom activities; self-assessment of actual and potential success in science-related activities; perceptions of the quality of the science teacher(s) encountered; and reaction to the attitudes of their peers and parents toward both science and science

education. Evaluating the research that has been done into these factors is not easy. Are the identified attitudes toward science/science education in general or are they focused on individual science subjects, e.g., physics, chemistry, biology, and their presentation in the curriculum?

Students' attitudes toward school science seem to decrease from the start of formal schooling (Pell and Jarvis, 2001) and to continue throughout the secondary (high) school phase (Yager and Penick, 1986), although it does seem that biology is rated more positively than the physical sciences (Osborne and Collins, 2001). A worldwide study (Sjoberg and Schreiner, 2010) showed that such attitudes declined throughout the span of schooling in industrialized counties (but not in developing countries), with that of girls being particularly steep. Other studies have thrown some light on the influence of specific factors, e.g., the family (Archer et al., 2012) and ethnicity (DeWitt et al., 2010), on these trends.

Content and Organization

Although there had long been calls for curricular change (e.g., Schools Council, 1970), which had been proceeding unevenly over the years, it was the report 'Beyond 2000' (Millar and Osborne, 1998) that called, amongst many things, for an emphasis on key 'explanatory stories'; the nature of scientific inquiry; the relationships between science and technology and their implications for everyday life. The influential Rocard Report (Rocard, 2007) set these suggestions in a Europe-wide context and added emphases on the relationship between the formal and informal provision of science education and, particularly, on that for girls.

The progressive implementation of these changes has been underpinned by three developments. The first of these was the clarification of the distinction between the two types of curriculum: that based on 'Vision 1,' drawing heavily on orthodox science and intended to provide prevocational science education; that based on 'Vision 2,' drawing heavily on those aspects of the everyday lives of students for which science had relevance (Roberts, 2007). The second of these has been the development of 'context-based' courses, in which the learning of key concepts is framed within the study of situations, problems, events, that have meaning for the students (Gilbert, 2006). The third of these was the focus on 'socio-scientific issues' in which the emphasis was on the social aspects of the nature of scientific inquiry and on the implications of science for the lives of individuals and societies (Sadler, 2009). Taken together, these three developments are claimed to have successfully addressed the challenges faced by science education although they have been rarely implemented in full and therefore cannot have been thoroughly researched.

Little, if anything, has been written about the practical organization of formal science education since the introduction of the national curriculum. While the provision of 'separate subjects' (i.e., physics, chemistry, biology) still takes place, particularly toward the end of the high school period, there is little evidence of the provision of 'integrated science' courses, the majority being 'modular,' with themes from the separate sciences being interspersed. Whilst it is common for all children of primary (elementary) school age to experience the same curriculum, the continuation of that format in the high (secondary) school soon gives way to 'core' courses, supported by 'optional' courses, enabling students following 'Vision 1' courses' to be progressively distinguished from the majority taking 'Vision 2' courses.

Relationship to Technology

Science can be seen as the search for understanding of the world as experienced. Technology can be seen as attempts to meet the practical needs of individuals that arise in a wide range of different physical, social, and cultural milieus. The meaning of the latter has been obscured somewhat by the North American misuse of the word 'technology' as equating with 'computers.' Science and technology as activities are related, albeit in a number of different ways (Gardner, 1994), all of which have implications for how the two activities are related in the school curriculum.

Historically, most school science teachers have viewed technology as applied science. This has led technology education to be seen as the addition of examples of technologies as appendices to topics in the science curriculum. Although this view does have a very limited validity, there have been calls to take a broader perspective on the relationship (Cajas, 2001). One solution has been to introduce the separate subject of technology into the curriculum, called 'Design and Technology' in England and Wales. However, this approach seems unlikely to succeed in the long run because of the time constraints arising from the complex relation between the concepts used in the two subjects, from the length of the school day (technology activities require sustained periods of time), from the lack of clear recruitment lines for suitable teachers from higher education, and because of the large investment in physical plant required, all of which were anticipated by Layton (1993). An approach which seems more likely to succeed is through the provision of modules, prepared by working groups, in which science and technology are brought to bear on themes about contexts of specific socio-scientific interest. An example is the 'Nature, Life and Technology' course available to both Vision 1 and Vision 2 audiences in the Netherlands in the form of 66 modules, prepared by groups of school and higher education teachers, and adopted by 44% of all senior high schools (NLT, 2008).

Nature of Science

Calls for school science education to place a much greater emphasis on how scientific knowledge is generated and validated are of long-standing duration (e.g., Schools Council, 1970). The failure to do so that has resulted reflects both the tenacity of 'folk knowledge' about science by both teachers and students and the lack of agreement about what the phrase actually encompasses and how it might be taught. Folk knowledge about science stems from two sources: first, from the persistence of 'indigenous knowledge,' i.e., those explanations about nature that stem from tenacious belief systems other than those of science (Cobern and Loving, 2000); and second, from the misrepresentations of nature of science that persist in textbooks, e.g., the ideas that scientific knowledge is produced by a process of induction from the results of

empirical enquiry, that scientific theories are truthful and unalterable, and that scientists work alone. The persistence of such ideas stems from the failure of philosophers, historians, and sociologists to come to any sort of agreement on the meaning of the phrase 'nature of science,' both amongst and between themselves. This uncertainty goes unchallenged as few future science teachers are required to take any courses on nature of science.

The currently available consensus view, which avoids major disagreements and which is used in much science education research, is that science knowledge is subject to change; has to account for empirical observations; is influenced by scientists' personal views; is proposed by acts of imagination; and in validated by discussion between scientists (AAAS, 1990). Two broad approaches to teaching nature of science have emerged over the years: providing students with opportunities to conduct scientific enquiries and of then reflecting on what they had done; and direct instruction in the main ideas of the consensus model. A review of many studies came to the conclusion that it is a blended amalgam of the two approaches that is the most effective approach (Abd-El-Khalick and Lederman, 2000).

Models and modeling is one aspect of nature of science that has made good educational progress. A scientific model is a representation of an idea, an object, an event, or a process, initially produced for a specific purpose in research, the ontology of 'model' having been explored (Gilbert and Boulter, 2000). Early work showed that the 'nature of model' was not well understood by either teachers (e.g., Crawford and Cullin, 2005) or students (e.g., Grosslight et al., 1991). Systematic interventions to remediate this situation proved very satisfactory in respect of teachers (e.g., Justi and Van Driel, 2005) and students (e.g., Raghavan and Glaser, 1995). Approaches to the development of modeling skills have been proposed (e.g., Justi and Gilbert, 2002) and successfully implemented (e.g., Menonca and Justi, 2013).

A second aspect of nature of science that is making progress – it is not clear how rapidly and successfully – concerns practical work in the context of inquiry-based teaching and learning. Since the outset of formal science education, laboratory work has been defended as a major component of the subject. It has been included in the curriculum for a number of reasons: to provide opportunities to acquire conceptual knowledge, to develop the skills of empirical inquiry, to introduce students to some aspects of how scientists actually go about their work and, perhaps most importantly, to engage the interest of students in the subject. It was perhaps because this array of objectives was indiscriminately addressed that the outcome was a high degree of uncertainty over the educational value of practical work as such (Hofstein and Lunetta, 1982). This is unfortunate given the high cost of providing laboratories and equipment. In the last decade or so, 'inquiry-based teaching and learning,' which implies a central role for the laboratory, has become a major element in the national curricula of all countries.

Implementing inquiry-based learning – attempting to replicate the activities of scientists in schools – is only slowly and hesitantly being introduced, for a number of reasons. There is no clear agreement on what that replication entails, although Bell et al. (2010) have suggested that it consists of nine elements in varying order: posing a question; generating a hypothesis; planning the inquiry; carrying out the investigation; analyzing and interpreting the data obtained; producing a model of the phenomenon; drawing conclusions as to the answer to the question posed; communicating that answer to others; and making predictions about the phenomenon based on that answer. In addition to the major problems of identifying phenomena that are suitable for inquiry within the restricted resources available in schools, the behavioral norms and social roles in many schools militate against such an approach to learning. For example, teachers will have to avoid taking the verbal initiative in classes too often, an approach that many will find difficult (Van Zee, 2000), while students will have to acquire the ability to discuss scientific issues meaningfully amongst themselves (Roychoudhury and Roth, 1996). The more authoritarian educational systems will find the introduction of inquiry-based teaching, as many are attempting to do, particularly challenging. In all cases, it may well be desirable to change existing procedures gradually.

Assumptions about Learning and Their Implications for Teaching

The traditional view about how learning takes place, in science as elsewhere in the school curriculum, has been based on the 'behaviorist' psychology of Skinner (Skinner, 1971). This assumed that a student was a '*tabula rasa*' ('blank slate') with respect to a specific idea until it had been systematically taught. That teaching would involve the careful and structured presentation of the new ideas, requiring their recitation by students until a perfect 'copy' was obtained, this process being supported by the measured use of rewards and punishments. Despite its rigorous and widespread application, attempts at learning by many science students have been unsuccessful when they have followed its precepts. In the late 1970s it gradually emerged that, in respect of many ideas that formed part of the science curriculum, students already had some understandings, albeit somewhat idiosyncratic in nature from the point of established science, before they were taught a specific idea. These came to be called 'misconceptions' or 'alternative conceptions' and were widespread, even universal, in occurrence (Gilbert and Watts, 1983) and they served to 'interfere' with the teaching being provided.

The three main alternative approaches to psychology came into prominence to account for these 'alternative conceptions.' They share the assumption that people learn by being mental active, not passively as behaviorism had assumed, and all provide accounts for how new knowledge is related to what is already known. They differ both in the relative importance of the individual in that process and that of the surrounding society.

The long-established ideas of Piaget (1929), which underpin all manifestations of what came to be called the 'constructivist movement,' place considerable emphasis on the role of the individual in learning, but do recognize the great educational value of interaction with the surrounding environment, of which other people form an important segment. However, much of his extensive empirical work was framed so as to provide support for his basic tenet: that the quality of understanding achieved was constrained by an individual's general 'stage' (as he put it) of mental capability at any one time, this

evolving roughly stepwise over the years of childhood and adolescence. The implication for teaching was that the demands made of the students could not exceed the capability of their current 'stage.' It was not clear what could be done to enable students to reach the next 'stage.' It was the rigidity of the 'stage' caveat, shown to be of doubtful validity, e.g., by Driver (1978), that led to its gradual replacement as the basis for research, initially by the ideas of Kelly and subsequently by those of Vygotsky.

Kelly (1970) focused on the individual as the major agent in learning; hence, his view is called 'personal construct psychology.' As he put it:

> Constructive alternativism holds that man (sic) understands himself, his surroundings and his potentialities by devising constructions to place upon them and then testing the tentative utility of these constructions against such *ad interim* criteria as the successful prediction and control of events.
>
> p. 1

He thus rejected any notion of 'stages' in an individual's development, seeing the pragmatic inclination to engage in prediction plus the testing of ideas as determining what can be learnt. He did accept the significance of other people in the learning process, with the caveat that:

> To the extent that one person construes the construction process of another he may play a role in his social process involving the other person.
>
> p. 2

With the 'stage' idea seemingly discounted, the social dimension to learning moved center stage in the 'social constructivist' approach of Vygotsky (1986). This saw learning as a process of social enculturation of a learner by interaction with an authority, e.g., a teacher. Only that knowledge which lies within the 'zone of proximal development' of the learner, a phrase the meaning of which is much debated, can be learned. One major consequence for teaching of the Kellian and Vygotskian approaches has been the acceptance that, for effective learning to take place, the teacher must identify what a student already knows about a subject and relate to that when introducing new knowledge. This has led to the development of clear procedures for identifying and remediating dysfunctional 'alternative conceptions' (Vosniadou et al., 2007). Meanwhile, efforts to locate students' zones of proximal development have been one of the major purposes for assessment.

Assessment

'Formative assessment' is the identification of students' knowledge about a given topic, the intention being to subsequently take action to improve that understanding. Teachers carry it out continuously during lessons, mainly through verbal questioning, and amend their subsequent teaching in the light of what they find out (Black, 1998). For formative assessment to be valid, the students must trust that the information they reveal – deliberately or accidently – will be used for their benefit. Alas, there is a paradox here, for such information can also be used to comparatively evaluate the performance of the students, which is 'summative assessment' and which is the lynchpin of institutional accountability (Bell and Cowie, 2001). Maintaining a reputation for integrity with students – a condition for retaining their trust – poses a professional dilemma for science teachers.

Whilst all educational systems include public examinations at specific intervals in the educational process, there has been a recent growth of very large-scale international systems of student assessment. The 'Trends in International Mathematics and Science Study' (TIMSS) of students in the fourth and eighth Grade, was first administered in 1995 and at 4-year intervals thereafter. It is focused on what students know of the concepts of a common core curriculum in the two subjects: an entry into the archive is provided by TIMSS (2013). The 'Programme for International Student Assessment' (PISA) study, organized by the Organisation for Economic Co-operation and Development (OECD), involves eleventh Grade students and is conducted every 3 years, starting in 2000. PISA examines the ability of students to relate what they have learnt at school to real-life situations: see OECD (2013). Both systems publish their results country by country. Students of a few countries/districts, e.g., Singapore, Hong Kong, South Korea, always do very well in these surveys. All the countries taking part in these schemes view their 'league position' as a matter of national pride and introduce reforms intended to emulate the schools of the most successful countries, i.e., in reality the increased use of behavioral psychology. It is a matter of interest that, whilst this is going on, the most 'successful' countries are moving away from such approaches.

Science Teacher Education

University graduates who become science teachers do so from a wide variety of academic backgrounds. Given that national curricula are intended to provide a fairly uniform provision of education, intending and actual science teachers normally go through a process of professional development which may be based either in a university or in a school. Whilst that education is often divided into two sections, a compulsory 'preservice' phase and a less rigidly managed 'in-service' phase, a strong case can be made for a more coordinated provision.

Such a provision can be provided with respect to three components: first, the 'professional' element, directly concerned with teaching and learning; second, the 'personal' element, concerned with the individual's perception of him-/herself as a teacher; and third, the 'social' element, concerned with the individual's perception of him-/herself as a member of a community of teachers. An orchestrated program of 'teacher professional development' can provide an evolution of professional identity across the pre- and in-service phases: in well-funded environments, this does take place (Bell and Gilbert, 1996).

That provision should be concerned with four themes. First, the teacher's knowledge of the subject(s) they are to teach. Many teachers have to work in schools outside their specialized field of undergraduate study. Moreover, they may not have a suitable depth of understanding of key concepts, for these

may not have been revisited since their own school days. Second, they will need to be introduced to the wide range of teaching techniques that are now in use. Third, they will need help in adapting concepts into a form that students can understand: they will have to deploy their so-called 'pedagogic content knowledge' (Shulman, 1987). Fourth, it will be necessary to ensure that their personal beliefs about science education are compatible with the assumptions of the curriculum they will have to teach.

Successful science teachers – those who remain in the profession for many years and enjoy the experience – will have had such an experience (Gilbert, 2010).

Research in Formal Science Education

The established pattern of research in science education – as in the rest of education – makes use of two contrasting approaches. Qualitative research, small scale, often case study, is intended to establish the nature of educational events and to identify concepts that can be used to represent them. Quantitative research, large scale, is intended to establish the incidence of educational events and the relationships between the concepts that represent those events. 'Mixed method' research uses a combination of these two types. For a wide variety of reasons, neither policy makers nor practicing teachers make much use of published science education research (Levin, 2013). Recently, researchers have begun to use 'design-based research' as the organizational framework for their activities (Cobb et al., 2003). Design-based research rests on five guiding principles. First, it seeks to solve real-world problems by making interventions into educational systems and evaluating their outcomes. Second, it is theory driven, intending that theory will be advanced. Third, it is interactive, in that the work is carried in a partnership between researchers and practitioners. Fourth, it uses a variety of existing research methodologies. Fifth, the outcomes of such work are context dependent, such that reports of what was done and why it was done must include full accounts of the educational situations in which it took place (Wang and Hannafin, 2005). It will be some time before enough examples of such work will have been published and conclusions drawn about whether it overcomes the established problems of the use of research.

The Provision of Informal Science Education

The Rise of Informal Science Education

Informal science education was first provided for adults in the nineteenth century (Layton, 1973). The development of the notion of 'museum' and the availability of cheap paper-based publications were major factors in extension of the genre, first into family-based education, and then directly into the education of school-age students.

Provided for a wide variety of purposes and in an ever-increasing range of ways, informal science education, in its purist form, has a number of characteristics that differentiate it from formal provision. It is voluntary, in that the learner decides what to learn, when, and how; based on experiences and themes that are presented without structure or sequence, so that the learner has to decide what to do; open-ended, in that the learner decides when to start and when to stop; and not certificated, so that any assessments made are only for the benefit of the learner (Wellington, 1990).

With respect to school-age learners, the increased incidence of informal science education can be attributed to the interplay of a range of factors. Science and technology advance at an ever-faster rate, producing ideas and artifacts that are of interest to young people. The development of the formal science curriculum cannot keep up, not least because the new ideas require elaborate and expensive illustrations and equipment, which national educational systems are unable, or unwilling, to afford. Private agencies will afford to do so, often in anticipation of being able to charge fees for access. The element of voluntary choice and decision by a young person leads to their engagement in learning, thus counteracting declining attitudes to science education. Perhaps most importantly of all, a young person can choose to actively learn with somebody else – family member or friend – whilst the formal education system largely prohibits this. Whilst some informal resources are based on behaviorist principles, for example when the direct transmission of factual knowledge is involved, the great majority make use of social constructivist principles, requiring the active engagement of the learner – alone or with others – in order for the experience to advance. This flexibility in terms of psychology of learning has led to a wide range of types of provision. In the next two sections, a sketch of the main forms will be given.

Provision through Conventional Media

Provision of opportunities for science education by museums, botanical gardens, and zoos can be grouped together because they all contain original objects, inanimate or animate, about which the visitor is invited to construct a narrative with the aid of a brief explanatory text. In the case of museums, an innovation in the last 20 years has been the addition of the 'science center,' in which exhibits require visitors to take particular actions and then providing feedback on the consequences of the actions taken (Rennie and McClafferty, 1996). Members of this grouping provide the maximum opportunity for visitors to learn together in self-organized groups.

Provision through 'popular books,' newspapers, and magazines may be grouped together because they are all paper based and accessible through a wide variety of outlets, e.g., newsagents, supermarkets, and train stations (Afonso and Gilbert, 2013). Their great attraction is that their timing of use is entirely in the hands of the learner.

Provision through Electronic Media

This large and very important grouping includes radio, television, the Internet, and computer games, all provided through electronic media. Of the long-standing media, radio is of particular value in providing access to learning for very low-density populations, e.g., Australia, or for very large and culturally complex countries, e.g., India. The advent of television so soon after the introduction of national radio systems has so far blighted the development of this medium for the provision of science education (Mazzonetto et al., 2005). Film and television may be grouped together because their content

and range of program types overlap, e.g., documentaries, news broadcasts, and movies. Television, in particular, has been found to be a valuable source of information and understanding (Dhingra, 2006). Of all the electronic-based media, the newest, the Internet (Hsi, 2007) and computer games (Connelly et al., 2012) are probably having the greatest impact and developing at the fastest rate.

Historically, there has been relatively little research done into the use and impact of informal learning resources, both in general and in science education in particular. The book *Learning Science in Informal Environments* is the most comprehensive account to date (Bell et al., 2009).

The Relationship between Formal and Informal Science Education

Because of the general underfunding of development for the formal science curriculum, an increasing use is being made of informal resources by co-opting them into the formal system. Where 'school visits' are made, for example to a science center, the greatest impact on learning is achieved by careful timing of the visit in relation to the coverage of the curriculum. However, it seems that most use of such recourses is made by students at their own initiative, thus retaining many of the elements of genuine informal learning (Stocklmayer et al., 2010).

In educational terms, the relative significance of the formal and informal systems will swing toward the latter, given the entrepreneurial initiative that drives the latter and the bureaucratic inertia that infests the former.

Abstract

Interest in the geography of science has increased significantly over the past 20 years to create a highly interdisciplinary field of inquiry. Rejecting the spatial determinism of earlier work, geographers and many others have developed insights from the sociology and philosophy of science and from social and cultural theory to examine the spatiality of science in all of its diversity and complexity. Particular attention has been paid to the sites at which scientific knowledge has been produced, assessed, and consumed and to the transmission of science over physical, cultural, and cognitive terrain.

Introduction

Work on the geography of science over the past 20 years or so has staked out a now flourishing area of academic research (Livingstone, 2003). Scholarship on the historical geography of science has been among the most vigorous in this burgeoning field. More recently, geographers and others interested in the development of technoscience in the recent past have added to our understanding of the spatiality of scientific knowledge and praxis. This diverse body of work has been guided by a shared assumption that determining where scientific knowledge is acquired, assessed, and applied carries significance beyond a simple mapping exercise. This assumption appears, on first encounter, rather puzzling. The truth of scientific knowledge is typically understood to be independent of local circumstances or geographical contingencies.

This view, however, is at best incomplete. Scientific knowledge is always a hard-won accomplishment. To make a claim that is robustly scientific requires the mobilization of material resources, technology, institutions, and personnel. Science thus relies upon distinct and intricate spatial arrangements and, in turn, significantly transforms the places where it is made, modified, or marketed. Investigating the geography of science involves, then, unearthing the spatial conditions necessary for the relative success of particular scientific claims or projects. Before offering examples of work that takes that task seriously, filling out the historical background and conceptual foundations of recent research on the geography of science will help highlight some important theoretical underpinnings.

Histories, Theories, and Concepts

While most academic work on the geography of science has occurred in the last two decades, it is possible to identify a longer, if discontinuous, history of interest in the geography of science reaching back to the late nineteenth century. In a study published in 1873, the Swiss phytogeographer Alphonse de Candolle concluded that Europe's leading men of science had been largely confined to a triangle with a base running from Sweden to Scotland and an apex terminating in central Italy. For Candolle, the particular social and natural environment of Western Europe was the leading cause of this golden triangle of scientific excellence. Such an approach and general argument had advocates in the twentieth century including the social geographer Stephen Visher and the historian of technology, Harold Dorn. For Visher and Dorn, the geography of science referred to the influence of different kinds of physical or cultural environments on the level and concentration of scientific ability or on the distribution of specific types of scientific inquiry. The drift in this work toward spatial or environmental determinism made it unpalatable to others interested in understanding the development and growing influence of science in the modern world. By contrast, a concern with the geography of science born out of a sustained engagement with the sociology of scientific knowledge and its more recent offshoots have helped to nurture a more lasting research program.

The sociology of scientific knowledge, which emerged in the early 1970s, rested on the assumption that science was 'constitutively' or inescapably social (Shapin, 1995: p. 289). This was a radical departure from earlier sociological accounts of science, which accepted that scientific error could be explained by social factors but which assumed that properly validated science was by definition free from the taint of social or cultural influences. Proponents of the so-called strong program extended the argument that science, like any other human activity, was a fundamentally social enterprise (see Barnes et al., 1996). Arguing against making a priori judgments about the truth of certain bodies of knowledge, they aimed at social accounts that explained equally the success or failure of competing scientific claims. The underlying premise that science was social 'all the way down' also encouraged a 'localist' turn among sociologists of science (Shapin, 1995). If science was manifestly a social enterprise, it was also unavoidably 'local,' rooted in specific cultural circumstances and distinct sites of knowledge production.

In short, the realization that scientific knowledge was a form of situated knowledge (Haraway, 1988) highlighted the importance of geographic context for sociologists and historians of science (e.g., Smith and Agar, 1998). It also led to calls for geographers to take seriously the spatiality of scientific knowledge (Livingstone, 1995). At the same time, and not entirely independent, the nature of space and its role in social and cultural life in late modernity was being rethought by a number of influential thinkers within and outside of the discipline of geography. This so-called spatial turn involved

reconceptualizing space by overturning the view that regarded it as an empty or inert container for social action. Influenced by the theoretical interventions of Henri Lefebvre and others, space was redefined as part of the action, made and remade along with social and cultural life. The spaces of science, in this way of thinking, were no longer viewed simply as a backdrop to scientific change but were now analyzed as a key ingredient in the unfolding dynamics of scientific cultures.

A number of the architects of the spatial turn strongly influenced geographers and historians and sociologists of science interested in the spatiality of scientific knowledge. To name but two, Clifford Geertz's 'thick descriptions' of diverse social groups, which carefully excavated the local frames of reference that governed cultural behavior, proved useful for constructing ethnographies of scientific communities. And Michel Foucault's archaeologies of venues that facilitated the emergence of modern forms of power and surveillance provided inspiration for those trying to understand the constitutive role of particular spaces in the making and meaning of science.

The rethinking of space as an active part of science in the making also showed that carefully reconstructing the circumstances that shaped different sorts of scientific projects involved more than the reductively 'local.' In other words, the location of science could not be reduced to a set of numerical coordinates. Instead, it had to be approached as a product of social relations and scientific practices that were at once located in a given place and distributed across space. Sociologists of science also quickly realized that the multiplication of individual case studies detailing the situated nature of particular scientific initiatives could not offer a compelling explanation for one of the most remarkable features of modern science – its efficient and secure transmission from one place to many others (e.g., Harris, 1998). Science was, after all, widely supposed to be a global, because universal, form of knowledge. The geography of science had to include not only a detailed account of the lineaments of self-contained social spaces and circumscribed venues but also an understanding of the character and extent of wider networks of scientific exchange and communication. Bruno Latour (1987) was among the first to supply a set of theoretical resources to help examine the distributed nature of scientific research. In particular, Latour pointed to the creation of 'immutable mobiles' – fixed units of scientific information readily combined with similar units derived from other distant places – and to 'centers of calculation' where these units are collected, collated, and classified. Peter Galison's (1997) proposal that science relies on successful negotiations within a 'trading zone' offered another approach to understanding the efficient exchange of results, methods, and ideas across different scientific subcultures.

Broadly speaking, then, the geography of science can be analyzed using two relatively distinct modes of inquiry. The first is concerned with situating science in particular sites, places, and institutions. The second is concerned with tracking the movement of science across space. Some examples will illustrate what might be involved in pursuing these lines of investigation. As will become clear, however, this heuristic distinction between sites and movements, and between local and global knowledge, has its limitations and methodological blind spots.

Situating Science

A key claim underlying much recent work on the geography of science is that precisely where scientific knowledge is generated, transacted, applied, or consumed is of considerable importance. Science is always made somewhere, and opening up the 'black box' of those discrete settings can reveal a great deal about the nature and meaning of scientific research.

Among the huge range of sites where scientific knowledge has been, and is, generated, the laboratory is perhaps the most obvious. Designed to provide a carefully controlled environment for the production of accurate and precise knowledge about the world, the lab is often thought of as the archetypal space for conducting scientific research. Partly for this reason, it was among the first scientific sites to be explored by sociologists interested in the social dimensions of scientific knowledge production (e.g., Woolgar and Latour, 1979; Knorr-Cetina, 1981). If the social character of laboratories designed to filter out influences that might 'contaminate' scientific procedures could be determined, then the case for regarding science as an irreducibly social enterprise could be more strongly made.

What rapidly became clear through these studies is that 'the laboratory' does not refer to a single, stable space but rather to a diverse set of venues operating according to different codes of conduct, cultural norms, and epistemic protocols. Even the most carefully managed modern laboratory was found to have its own distinctive research culture and acted as an important social institution for determining scientific questions and scientific careers. The 'micro geography' of the lab – understood not just in terms of physical arrangement of rooms and equipment but also the social interactions of lab workers – proved to be of vital significance. This finding, of course, runs against the grain of the ideal to which those designing and running laboratories aspire, namely, to create a 'placeless' place entirely isolated from a messy and chaotic world (Kohler, 2002). Yet there is, as it turns out, an interesting geography to the pursuit of that ideal.

If laboratories are created to control the messiness of place, field sites might be thought of as a kind of antilaboratory, a space in which variability or contingency is preserved for the purpose of scientific study. Scholars interested in this contrasting 'site' of scientific inquiry have noted that fieldwork is an inherently risky intellectual venture pursued without the security of controlled conditions, carefully defined protocols, or the infrastructural support provided by a modern laboratory (Kuklick and Kohler, 1996). Historical studies have shown that the basic spatial division between laboratory spaces and field spaces emerged early in the history of modern science and was also apparent in the methodological preferences of different practitioners. The apparently fleeting, partial and idiosyncratic observations made in the field were regarded by some as untrustworthy and of limited value. Defenders of fieldwork responded by arguing that out-of-door observations provided data on 'raw nature' and brought the investigator closer to nature's realities than did the isolated researcher working under artificial conditions in the study or laboratory (Outram, 1996). However valued, the open-ended and unpredictable character of field spaces forcibly underlines the situated character of scientific inquiry, its 'craft competencies,'

tacit rules of action, and its responsiveness to changing local conditions (Livingstone, 2003: p. 45).

The contrast perennially drawn between field sites and laboratories also helped to form a certain sort of scientific investigator. Strategies to counteract charges of hasty observations and uncertain and unrepeatable findings included emphasizing the heroic exploits necessary to get to, and remain in, isolated and challenging field environments. These strategies were taken a stage further with the creation of other distinctive sites for scientific inquiry such as the field station, observatory, and mobile laboratory. Field stations, for example, combined the 'virtues' of lab and field to produce a hybrid venue marked by a kind of controlled adaptability. They created an experimental complex positioned, as Henke (2000: p. 484) puts it, between 'the standardized space of the lab and the messiness of the field.' The astronomical observatory emerged from a desire to offer a controlled and replicable site for making precise measurements and observations in remote places. For all that, while appealing to the rhetoric of precision associated with the laboratory, late-Victorian astronomers also described themselves in terms of the 'explorer scientist' and 'heroic fieldworker' (Lane, 2010). And the mobile laboratory on research vessels like the *Challenger* merged different ways of knowing and functioned within a distinctive social environment created by the uneasy relations between scientists and sailors (Rozwadowski, 2005).

Other spaces of scientific inquiry have been defined as much by the task of attracting public interest as by efforts to produce credible and robust knowledge. This has generated additional challenges, competencies, and patterns of inquiry. Museums provide a classic example of a scientific space that formed at the intersection between the quest for knowledge about nature and the desire to display that knowledge to a general public (Forgan, 2005). Emerging from early modern cabinets of curiosity, museums by the nineteenth century became key sites for nurturing the natural sciences and fashioning a certain sort of citizen. European metropolitan museums in particular became linked with nation building by indexing national progress through vast collections of carefully arranged natural and cultural artifacts. They also operated within a marketplace of ideas and institutions, competing with other public attractions such as the circus or freak show. Striking a balance between entertainment, instruction, and original research helped to shape internal spatial arrangements and influenced the direction, success, and wider meanings of museum research. At the same time, the micro geographies of display were also shaped by scientific disputes. The Natural History Museum in London is classic case in point. In the late nineteenth century, the director, Richard Owen, arranged the collections of organic specimens according to his own particular account of the relations between extant and extinct plant and animals (Yanni, 2000). The displays materialized Owen's dissent from Darwin's theory of evolution and promoted his own program of natural historical research.

Botanical and zoological gardens appeared in the same period as museums and, in a similar fashion, were fundamentally shaped by cultural as much as scientific concerns. As Johnson (2011) has shown, botanical gardens were constructed with both aesthetic and taxonomic imperatives in mind. With the emergence of glasshouses, gardens were also able to accommodate exotic flora, a fact that appealed to visitors as well as enabling research on tropical as well as temperate vegetation. Zoos, too, traded in the exotic, retaining an emphasis on unfamiliar fauna from the menageries from which they emerged. The scientific study of the living world was thus accompanied by a set of changing cultural expectations associated with a public's appetite for viewing exotic plants and charismatic animals.

A host of other less obvious sites where scientific knowledge has been assembled or assessed have also been interrogated by scholars interested in the mediating role of space in the making of modern science. The public house, the kitchen, and the courtroom have, for example, revealed a set of social scientific relations mediated by, respectively, artisanal sociability, domestic economies, and legal regimes. But situating science in its diverse contexts of production and dissemination need not be restricted to the micro scale. Cities and regions have also been studied as 'sites' in which science has been pursued or promoted. Science has, in the words of Lafuente and Saraiva (2004), played a 'fundamental role in the definition of urban spaces.' In the late-nineteenth-century Madrid, for example, scientific institutions functioned as heterotopias, 'symbols of a promised metropolis' (Lafuente and Saraiva, 2004: p. 531). The 'shock' cities of industrial Europe in the nineteenth century presented challenges that encouraged the rise of the 'civic scientist' with expertise in urban problems. Further, cities have become both field sites and laboratories for a variety of scientific research programs. The Chicago School of urban studies, for instance, was closely tied to the study of the city in which it was based and worked to create a 'truth spot' at an urban scale that would secure the school's credibility among other social scientists (Gieryn, 2006). Cities and regions have also helped to shape the varied reception of scientific knowledge. This has been demonstrated in abundant detail by Secord (2000) through careful reconstruction of the different responses to the anonymously authored evolutionary text *Vestiges of the Natural History of Creation* (1844) in the contrasting civic and religious cultures of Edinburgh, Liverpool, and Oxford. Livingstone (2005), too, has shown that responses to Darwinism in the American South, New Zealand, and Russia were determined in part by the religious and cultural milieux of those regions.

At whatever scale of investigation, it is clear that different sites of scientific inquiry come with their own distinctive suites of practices, protocols, and personnel. Situating science in the sites of its making thus requires attention to the specific arrangements that make scientific investigation possible and also demands attention to the ways in which scientific investigation helps to form and refashion the spaces in which it is carried out. But, as many have pointed out, the localist nature of such studies do not immediately provide answers to why modern science has been so successful and so influential (Shapin, 1998; Harris, 1998; Secord, 2004). More specifically, they do not address the question of why, if it is just another form of local knowledge, science has traveled with such unparalleled efficiency from one place to many others. Nor do they necessarily help us to understand how science earned its reputation as the quintessentially global form of knowledge. These patently geographical questions direct us to the demanding but essential task of tracing and interpreting the movement of science across space.

Tracking Science

As outlined above, detailed accounts of individual laboratories have helpfully troubled the notion that science, as a kind of birthright, floats free from the contexts in which it is made. But such micro studies have risked missing the ways in which laboratories are from the start 'plugged into' the wider world. Kohler (2008), for example, argues that laboratories should be understood, among other things, as an expression of late-modern capitalism. According to Kohler, "the analytic categories and practices of lab science were congruent with the new managerial hierarchies and procedures of large-scale industrial capitalism…[and] scientists proved useful allies for modernizers striving to transform the traditional business firm into the modern managerial leviathan" (p. 768). This analysis does not, however, apply straightforwardly to all laboratory cultures. Simon Reid-Henry's (2010) close reading of Cuba's biotech industry demonstrates that it functions according to the directives of a socialist state *and* the powerful norms of a global industry. Its 'strategic marginality' has allowed innovation and experimental creativity to flourish but not in ways easily translatable into the regulatory regimes of Western capitalism. Even so, the labs within Havana's biotech complex are thoroughly embedded in networks that stretch far beyond local horizons.

Arguably, work on field sciences has been alert from the start to the situated and mobile nature of scientific investigations pursued outside the laboratory walls. We have already noted that field sites have often been contrasted with laboratories in their unpredictability and 'messiness.' As Bruno Latour (1999: p. 30) puts it, in the laboratory 'one no longer sees science stammer.' In the field, the situation is different. There the 'gap' between science and the 'real world' clearly opens up. Fieldworkers face the formidable task of acquiring stable data for building robust theories about large-scale natural phenomena. The 'jump' from local to global knowledge cannot be done in a leap but involves a significant amount of hard scientific labor. In his account of field research in Brazil, Latour (1999) shows that the 'chains of translations' that connect the field site to the final published paper involve a series of small transformative steps. The field scientist moves through physical space (from field to home institution, for example) and, often more haltingly, across cognitive domains and between scientific disciplines. The creation of standard forms of measurement and transportable and comparable samples are among the many rather precarious techniques necessary to convert field observations into the printed diagrams and text of a scientific paper.

Fieldwork, involving as it does the traversal of real as well as cognitive terrain, can also quickly become entangled in matters not directly connected with the scientific task at hand. Historically, field exploration has been thoroughly embroiled not only in the development of scientific knowledge but also in the politics, ambitions, and at times brutal realities of colonialism. In this sense, doing scientific work 'in the field' cannot be separated from the much larger political and economic projects that, in ambition if not in fact, have spanned the globe. A classic case in point is the Great Trigonometrical Survey of India, begun in 1802 by the British army officer and geodesist William Lambton and continued for much of the nineteenth century. The ambitious aim of the survey, to determine the size and shape of the globe, was pursued alongside more mundane matters of colonial governance. The survey also provided material for an apologia for imperial expansion in the Indian subcontinent (Edney, 1997). The practical exigencies of geodetic measurements in the field were thus combined with a political project and political discourse that imbued the survey with significance well beyond its immediate practical and intellectual goals.

The kind of 'big science' carried out by British surveyors in India has been productively studied by other scholars interested in the ways in which scientific knowledge 'travels' well beyond the confines of the laboratory, field site, or study. In his work on early modern corporations, Steve Harris (1998: p. 271) has argued that "how science travels has as much to do with the problem of travel in the making of science as it does with the problem of making science travel." As Harris shows, the development of natural knowledge in the early modern period cannot be disentangled from the patronage and ambitions of 'long-distance corporations' such as the Dutch East India Company and the Society of Jesus, a Roman Catholic religious order. Mike Hulme's (2010) work on the geographies of climate change science is animated by a similar concern with the institutional settings from which 'global' knowledge claims emerge. Hulme contrasts the 'globalizing metrics' of officially sanctioned climate science with the local cultural values that shape people's responses to variable climatic conditions. Applying this to the Intergovernmental Panel on Climate Change, Hulme argues that insensitivity to a range of cultural perspectives creates a 'brittle' kind of global knowledge that cannot accommodate a 'plural and turbulent world.'

The politics of science, understood as a globalizing or 'totalizing' enterprise, has also attracted the attention of post-colonial theorists. Warwick Anderson (2009: p. 392), for example, has called for more attention to how "science and technology travel over the uneven terrain that colonialism has worked." By ignoring the legacies of European colonialism, scholars have neglected the continued impact of imperial forms of power on science. Historians of science have also underlined the importance of attending to connections between science and imperialism. Kapil Raj (2007), for example, has argued that in the eighteenth and nineteenth centuries scientific knowledge was a product of the unequal relations between Europe and the territories that it explored and colonized. At the same time, science was not simply a European imposition foisted on subjugated peoples. Nor was the knowledge of non-Europeans always cordoned off from, and alien to, Western science. Instead, science was made in intercultural contact zones in which the flow of ideas and scientific materials, while tipped toward European powers, moved in more than one direction.

Conclusion

Whether concerned with situating scientific knowledge or tracing its movements, the work summarized above reveals the importance of grasping the spatialities of science in efforts to uncover its profound but varied influence on late-modern societies. It has also become clear that the question of scale is a central one for work on the geography of science. Determining the most appropriate scale for investigating effectively

a particular scientific project is not at all straightforward. The site or sites at which scientific knowledge is produced may or may not have identifiable cartographic coordinates but a physical 'address' does not tell us much about the scale at which scientific inquiries are carried out. A laboratory may have its own 'local' cultures of research that are dependent upon a dense and widely distributed set of ideas, instruments, personnel, and methods. To overcome this difficultly, scale might be profitably regarded as an emergent property of the practice of science itself rather than something that exists independently from scientific work. There is a danger, however, that this constructivist account of scale may exaggerate the power of scientific practices to transform human politics and society. A related challenge concerns the applicability of accounts of the geography of certain scientific projects, practices, or debates to other cultural situations or to other scientific times and places. One criticism made of studies offering detailed reconstructions of scientific spaces in the past or present is that they tell us little about changing patterns that can only be discerned at a 'macro' level. As Daston (2009: p. 809) recently put it, for the average 'micro history' of science, 'the texture is fine grained, the metaphysics is nominalist and the aesthetic is pointillist.' Clearly, the difficult task of moving between scales, whether spatial or temporal, is faced by geographers concerned with investigating the spaces of modern science. This is not, of course, a new problem or one that is unique to science studies. Human geographers have long been concerned with the challenges of relating the particular and the general and while they clearly have no monopoly on approaches that might address this methodological quandary, they are well placed to offer some ways forward. Certainly, there is no reason to restrict the study of the geography of science to the 'pointillist' approach identified by Daston. Addressing these and other methodological issues will no doubt continue to prompt and guide further work in a scholarly field that is now a well-established area of geographical inquiry.

Abstract

The history of science is a small discipline with a large and expanding subject matter: not only the history of the modern natural and human sciences but also premodern and non-Western traditions of knowledge and learning. Because it lies at the intersection of the humanities and the natural human sciences, it has been and remains a locus of interdisciplinary research.

History of Science

The history of science studies the emergence and development of systematic knowledge. Just what kind of knowledge that is – whether it is defined by subject matter, reliability of results, contradistinction to technical know-how, cumulative progress, disciplinary consensus, and/or method of inquiry, demonstration, or explanation – is a point of persistent debate and reflection within the history of science and its cognate fields in philosophy, sociology, and anthropology. Linguistic and historiographic traditions diverge sharply on this point. Whereas Francophone and Anglophone scholars have since the mid-nineteenth century largely reserved the honorific 'science' for the natural sciences and mathematics (influenced by Auguste Comte's hierarchy of sciences in his *Cours de philosophie positive*, 1830–42, in which only some had reached the stage of 'positive' knowledge), the German *Wissenschaft* still refers to the range of fields covered by the Latin *scientia*, from physics to philology. Moreover, recent explorations of experiment and other practices have blurred the venerable boundary between *ars* and *scientia*, technique and systematic knowledge (whether understood narrowly as 'science' or broadly as *Wissenschaft*). Close investigation of the sciences even in the restrictive English and French usage has furthermore revealed considerable variety among methods and explanations in, for example, biology and physics. Finally, studies of premodern and non-Western intellectual traditions have made the creation of categories like 'science,' as well as the classifications of knowledge that order such categories, themselves objects (rather than presuppositions) of historical research. Hence this article will not attempt to delineate sharply the boundaries of 'science,' but rather briefly survey the (1) emergence and status of the history of science as a recognized field of inquiry; (2) principal divisions of the field and disciplinary affinities; (3) periodizations and narratives that have shaped those divisions; and (4) major historiographical developments since about 1970 (for an earlier survey see Kuhn, 1972 [1968]).

Emergence and Divisions of the Discipline

The history of science is an ancient pursuit, but a relatively young discipline. From Aristotle through the early nineteenth century, practitioners of one or another branch of knowledge have variously used the history of their field to argue for its dignity and importance, introduce it to beginners, situate it within a broader cultural milieu, summarize the literature to date, position themselves in relationship to that literature, praise and blame predecessors, give evidence of progress, extrapolate a program for future research, and draw lessons concerning the nature of knowledge and the conditions for its flourishing. In works like Joseph Priestley's *The History and Present State of Electricity* (1767) or Georges Cuvier's *Rapport historique sur les progrès des sciences naturelles depuis 1789* (1808), the history was inseparable from the science. Particularly in fields dominated by empirical research, the judicious sifting and ordering of past results was a precondition for coherence and a means for achieving consensus on what was reliably known and where the major challenges for future research lay. These functions are preserved today in the scientific review article and the posing of key 'problems' (e.g., the celebrated Hilbert problems in mathematics), and practicing scientists occasionally still appeal to the history of their field for present guidance, especially in times of crisis (Graham et al., 1983). By the mid-nineteenth century, however, histories of science had become distinct from scientific publications, although they were still written primarily by scientists, including prominent figures such as William Whewell, Marcellin Berthelot, Ernst Mach, and Pierre Duhem. Their histories often criticized the current state of science by establishing the genealogy of a controversial hypothesis (e.g., atomism), analyzing the origins of a suspect concept (e.g., absolute space) for hidden flaws, or pleading the superiority of one approach to science over another (e.g., Kantian ideas over Comtean facts). By 1900, histories of science had become a genre distinct from science, but they were still motivated by, and deeply engaged with, contemporary scientific developments (Laudan, 1993).

History of science coalesced only gradually as a recognizable discipline in the twentieth century, with its own distinctive program of training, institutions (journals, professional societies, university positions), and scholarly standards. Spurred by the organizational efforts of such scholars as Paul Tannery in France and Karl Sudhoff in Germany, there was a spurt of professionalizing activity around 1900, when the first international congress on the subject was held in Paris. The German Gesellschaft für Geschichte der Medizin und der Naturwissenschaften was established in 1901; the first chairs in the history of science also appeared at European universities around this time (Kragh, 1987). The Belgian historian George Sarton (Pyenson and Verbruggen, 2009), who emigrated to the USA after World War I, brought with him the journal *Isis* (est. 1912), which became the official organ of the North

American History of Science Society after its establishment in 1924 and remains the specialist journal with the largest circulation. Other journals dedicated to the history of science (including the history of the human sciences, which now boasts several specialist journals and societies) in all its aspects have since proliferated in many languages, to which the entries in the annual installments of the *Isis Current Bibliography* provide at least a partial guide.

Although Sarton's Comtean view of the history of science as a saga of intellectual and moral progress that should evaluate the past in light of present scientific understanding (Sarton, 1948 [1927]) has left little trace in current historiography (Dear, 2009), his tireless attempts to institutionalize and organize the discipline in the form of university departments, specialized journals, and research tools like the *Isis Current* (earlier *Critical*) *Bibliography* (History of Science Society, 1967), and *Dictionary of Scientific Biography* (Gillispie, 1981) had a lasting impact on the field (Thackray and Merton, 1972; Holton, 2009). During the 1950s, graduate programs dedicated to the history of science (sometimes in conjunction with the philosophy or sociology of science) multiplied; by 1990, there existed almost 200 degree-granting programs in 25 countries.

By no means all history of science is done under the auspices of university departments or published in journals expressly devoted to the subject. The disciplinary affinities of the history of science are many and mutable, with distinctive national differences. Until the 1970s, the primary connection, both in Europe and North America, was probably with the sciences themselves. This connection was rooted deep in the origins of the field and sustained by the continuing importance of some form of the history of science in the intellectual and social initiation of young scientists, as well as by the recruitment of historians of science from the ranks of those with scientific training. In the UK and North America, history largely replaced philosophy during the 1980s and 1990s as the discipline to which historians of science felt most akin (and within which the majority of them found employment), although interactions with sociology and, more recently, anthropology have also exerted a powerful influence, especially in connection with programs in science studies. In Western Europe, philosophy has remained a significant framework for the history of science, in diverse forms ranging from neo-Kantianism to logical empiricism, though science and technology studies have also been powerful influences since the 1980s. In Eastern Europe, Russia, Taiwan, and China, the history of science, sometimes with a national focus, has been cultivated within state-sponsored academies of science; in Latin America, Africa, and India science studies, postcolonial studies, and the history of medicine have often been the loci of academic teaching and research. In addition to its disciplinary polyvalence with respect to choice of problems and methods, the history of science is closely linked by its subject matter to the histories of medicine and technology, albeit to differing degrees depending on the historical period in question. The phrase 'science and technology studies' bears witness to these criss-crossing ties to other disciplines, serving as an abbreviation for the conglomerate 'history, philosophy, sociology, and anthropology of science, medicine, and technology,' which, however cumbersome, accurately reflects the ecumenical perspective of many historians of science.

Narratives and Periodization

Because of its links to philosophy, sociology, and anthropology, as well as to the natural and human sciences and mathematics, the history of science has been highly theorized for centuries. Theories about what scientific knowledge is, how it develops over time, where and when it expands and contracts, and in which ways it interacts with extrascientific contexts have profoundly shaped the way in which the history of science has been periodized and narrated. The more recent developments (since about 1970) in the historiography of science are incomprehensible without some background concerning the dominant theoretical schemes that had molded the field previously.

All history is inevitably written to some extent from the standpoint of the present, but present science – its orthodoxies and heresies, its controversies and critics – has exerted a mighty influence on the history of science since the Enlightenment. The great bulk of the history of science has been written explicitly or implicitly to illuminate, justify, or criticize the current state of science. In the Enlightenment histories, e.g., Jean-Étienne Montucla's *Histoire des mathématiques* (1758) or Jean-Baptiste Delambre's *Rapport historique sur les progrès des sciences mathématiques depuis 1789* (1810), the aim was to demonstrate that at least some of the sciences had shown steady and irreversible progress, especially since the Renaissance, and that the history of science was therefore a more edifying genre than the chronicles of human folly recounted by political and military history. The notion of progress was originally applied to art (by Giorgio Vasari in 1550) and to technology (by Francis Bacon in 1620), not to science. Once this interpretation of scientific change took hold in the eighteenth century, however, science became the premier example of progressive advance and scientific progress; a criterion by which to judge the comparative worth of civilizations. Whatever may have been the cultural achievements of the Latin Middle Ages or the Chinese empire, the stagnation of the sciences and mathematics in these milieux, so ran the argument of the Enlightenment historians, revealed fundamental intellectual and social limitations – limitations that in the nineteenth and twentieth centuries came to be described as characteristic of 'traditional' or 'premodern' societies. Hence narratives of scientific progress eventually became part and parcel of larger narratives about modernization and European superiority.

Although the assumptions underlying the Enlightenment vision of scientific progress are seldom invoked explicitly by contemporary historians of science, the reigning periodization of the field and the definition of specialties as central or peripheral still bears the traces of the traditional–modern division. Despite their glaring differences in many substantive aspects, the study of science in antiquity, the Arabic and Latin Middle Ages, and in non-Western traditions such as those of China and India has often been amalgamated into a shared problematic, one which defined science as peculiarly modern and Western by opposition (Elshakry, 2010). Only from this Eurocentric (and often ideologically self-serving) viewpoint do questions like the following make sense, although they

dominated the history of premodern and non-Western science until very recently: to what extent did the knowledge of these highly disparate cultures anticipate/approximate the science of post-Renaissance Europe? And to the extent that it did not, what were the intellectual and social obstacles that blocked the way? Hence the pioneering works in these areas (e.g., Duhem, 1908; Maier, 1949–58; Clagett, 1959; Needham et al., 1954) foregrounded possible forgotten contributions to and missing preconditions for the Scientific Revolution. Knowledge traditions that did not lead to modern science, understood to commence in early modern (a term as saturated with hindsight as 'the Middle Ages') Europe, were generally relegated to the periphery of the discipline, whatever their intrinsic interest and however excellent the scholarship devoted to them. As the scholarship on the history of Arabic, Chinese, and other non-Western, as well as premodern Western traditions has expanded, the parochialism of this perspective has been sharply criticized (Sabra, 1996; Lloyd, 2004; Sivasundaram, 2010; Chemla, 2012).

Despite such critiques, the Scientific Revolution has remained oddly central to the historiography of science. Oddly, because recent scholarship on Europe in the sixteenth and seventeenth centuries has emphasized the heterogeneity and regional variations in the developments in anatomy, astronomy, natural history, mechanics, chemistry, mathematics, and physics that were once summarily lumped together as 'the Scientific Revolution' (Lindberg and Westman, 1990; Porter and Teich, 1992; Shapin, 1996; Osler, 2000; Park and Daston, 2006). Moreover, the steep increase of studies of twentieth-century science since about 1980 has highlighted the novelty and significance of post-1900 developments, as the steady increase in the number of entries under these rubrics in the *Isis Current Bibliography* in the period 1990–2010 bears witness: whereas the number of publications under the combined rubrics 'Renaissance' and 'Seventeenth Century' (the time period embraced by the Scientific Revolution) have fluctuated between approximately 15 and 20% (with downward trend) of all the entries listed chronologically, those for 'Twentieth Century' and thereafter have risen steadily from approximately 30 to 40% (with upward trend) of the total.

Yet the Scientific Revolution retains much of the mythical status first granted to it by the Enlightenment historians as the mold in which modernity was cast, one of the few points upon which both the apostles of progress and the critics of modernity agree. This periodization has shaped the division of subspecialties within the history of science, which tend to be chronological or geographic ('ancient,' 'Southeast Asian') for knowledge traditions prior to, or uninfluenced by, the Scientific Revolution, but disciplinary ('physical sciences,' 'biomedical sciences') for those following that original event – even for disciplines (e.g., astronomy) with histories that long antedate the sixteenth century and with geographical distribution well beyond Europe. Recent studies of science on a global scale have put narratives and periodizations explicitly or implicitly oriented around the European Scientific Revolution under increasing strain, but a widely accepted alternative has yet to emerge.

The progress of the sciences (especially mathematics and the exact sciences) set forth by the Enlightenment historians was cumulative but not revolutionary. In their accounts, knowledge steadily expanded around a stable core of permanent truths, which may have taken millennia to discover, but which were thereafter firmly established beyond challenge. The language of 'revolutions' declined among early nineteenth-century scientists, perhaps in order to distance the permanent improvements of natural knowledge from the brusque reversals of politics; instead, the language of 'law' (e.g., Comte's 'Law of Three Stages') was applied to the historical development of science (Cohen, 1985). In the middle decades of the nineteenth century, however, this view of durable, inexorable scientific progress gave way to one of the rapid successions of scientific theories, even in areas (e.g., optics) long believed to rest upon unshakable foundations. Scientific progress had become vertiginous and open-ended; today's truth might be discredited as tomorrow's error. Under these conditions, it became increasingly difficult for historians of science to portray the steady growth of knowledge as culminating in present triumphs, since the endpoint was constantly changing. Instead, the history of science turned critical and conceptual: in the hands of Mach, Ostwald, and other late nineteenth-century scientist-historians, history of science revealed the past roots of present incoherences and taught the mutability of scientific theories. Within the revised interpretation of scientific progress, the purpose of the history of science was to use past science to change, not confirm, present science. Despite the dramatic shift in the narrative of scientific progress and in the goals of the history of science, its presentist orientation remained unchanged.

Almost all the strands of early twentieth-century historiography of science can be seen as attempts to come to grips with the peculiar character of scientific knowledge, which seemed to be simultaneously mutable and cumulative, driven by an internal dynamic and yet sensitive to ambient social conditions. These attempts often tugged in opposite directions. For example, the logical positivist program that stamped the history and philosophy of science in the middle decades of the twentieth century, especially in the modified form imported from the Vienna Circle to the UK and the USA, fixed upon the empirical findings of science as its enduring core in the Heraclitean flux of hypotheses and theories. These 'protocol statements' (Carnap, 1928) were likened to simple observations, bringing science into the neighborhood of common sense. In contrast, the French historian and philosopher Gaston Bachelard, drawing upon the insights of psychoanalysis, insisted upon the necessity of overcoming everyday experience and intuitions in the formulation of successful scientific concepts (Bachelard, 1938).

A many-cornered debate was ignited by the attempts of Marxist historians to relate the rise of modern science to specific socioeconomic conditions (Hessen, 1931; Bernal, 1939), out of which emerged the opposition of 'internal' to 'external' approaches to the history of science (Kuhn, 1972 [1968]; Shapin, 1992). External approaches found a non-Marxist model in Robert K. Merton's influential study of how science came to be valued in seventeenth-century England (Merton, 1938; Shapin, 1988). Informed by German and French neo-Kantian traditions in the history of philosophy, Alexandre Koyré's studies of the development of science in the broader intellectual context of early modern Europe stamped the work of historians of science, especially in France and the USA,

trained in the 1950s and 1960s (Koyré, 1939–40, 1961; Jorland, 1981). Common to all of these otherwise highly diverse perspectives on the history of science was an engagement with contemporary science and its lineage. Whether positivist or psychoanalytic, externalist or internalist, the history of science took the form of a genealogy leading to ideas and discoveries canonized by contemporary science. However much they may have disagreed on historical methods and forms of explanation, the combatants agreed on what and who in the history of science was worthy of explanation, namely that which had turned out to be pregnant with the future. In these histories, a potent telos was at work, making present science appear to be not only the actual but also the inevitable outcome of past developments.

Developments 1970–2010

Thomas S. Kuhn's *The Structure of Scientific Revolutions* (Kuhn, 1970 [1962]) broke decisively with this historiography, and stimulated new trends (not all to Kuhn's liking) in the history, sociology, and philosophy of science that have transformed the understanding of science and its growth in these fields since 1970. Kuhn argued for a plurality of scientific revolutions, in addition to *the* Scientific Revolution, which alternate with periods of 'normal science' framed by a 'paradigm' that models what can count as an acceptable problem, method, and solution in a given science in a specified period. It was less, however, Kuhn's 'structures' or patterns of long-term scientific development that exercised a deep and enduring influence on the history of science (although this feature of the book dominated its reception in other disciplines, particularly the social sciences) than his frontal attack on progressive narratives, his sketchy but evocative notion of 'paradigm' that embraced practices as well as theories, and the thoroughgoing historicism of many of his examples. All of these lines of thought were further cultivated in the history, philosophy, and sociology of science (the three disciplines were drawn into intensive interaction in part through their differentiated reception of Kuhn's book) during the subsequent three decades, often with consequences that led in directions diverging markedly from those plotted in *The Structure of Scientific Revolutions*.

Kuhn's rejection of progressive narratives in the history of science derived from his view that successive paradigms established and later overthrown by scientific revolutions were, first, internally coherent, and second, in a strong sense incommensurable with one another. This implied that science could not be cumulative in any progressive sense, one paradigm extending and building upon its predecessors. Kuhn's claim that conflicts between rival paradigms were not necessarily resolved by paradigm-independent criteria (e.g., predictive accuracy of explanatory unity) unsettled the inevitability of scientific development still further. Sociologists of science Barry Barnes and David Bloor took these claims as the basis of an approach called 'constructivism' (Golinski, 1998), in which the development of scientific knowledge was to be explained without appeal to its truth or falsehood, on the grounds that the truth of a proposition is neither a necessary nor sufficient condition for its acceptance (Bloor, 1991 [1976]). A protracted and ultimately inconclusive debate between 'social constructivists' (mostly coming from the sociology of scientific knowledge, or SSK, camp) and 'realists' (mostly philosophers of science) raged during the 1980s and early 1990s, ending not with a bang but a whimper (Hacking, 1999). In some circles, the debate was construed as a postmodernist attack on the sciences, triggering the brief but bitter 'Science Wars' of the mid-1990s (Wise, 1996). During the 1980s and 1990s, the history of science and science studies cross-fertilized one another in fruitful ways that spanned the premodern/modern divide. Articles devoted to science studies topics appeared regularly in *Isis* and *Social Studies of Science*, the flagship journal of science studies, returned the favor by publishing articles dealing with pre-1900 topics. Since 1996, however, the latter journal introduced an 'occasional series of "Historic Papers,"' under which rubric only three items appeared 1996–2010. Conversely, the 'Focus' section of *Isis*, initiated in 2004 to spotlight topics of over-arching interest in the history of science, has featured only a few themes with strong science studies affinities. Although the history of science was the battleground upon which all sides fought, arming themselves with historical examples to argue their points, these squabbles have had little lingering influence on how the history of science (as opposed to science studies) was pursued a mere decade later.

For historians of science, other aspects of the Kuhnian program have proved more fertile in the long run. First, in conjunction with Kuhn's focus on periods of conflict between rival paradigms, it prompted detailed studies of how scientific controversies were in fact resolved. Second, it enlarged the definition of what could count as 'science' for the purposes of historical investigation by ruling out hindsight judgments about what was and was not legitimate by present standards (to the benefit of specialties such as the history of premodern science and of the human sciences). Third, it encouraged a broader exploration of the grounds for scientific conviction by enforcing a 'symmetric' treatment of reasons for embracing false as well as true beliefs. This deliberate refusal to adopt the perspective of present science in the investigation of past knowledge went under the name of 'anti-Whiggery' among historians of science (in allusion to Herbert Butterfield's critique of 'Whig' political history). Among sociologists of science, the symmetry principle led to an increasingly distanced approach even to present science, to the point of adopting the ethnographer's estranged perspective (Latour and Woolgar, 1986 [1979]).

Kuhnian paradigms drew upon the philosophical reflections of Ludwig Wittgenstein (Wittgenstein, 1953) and Michael Polanyi (Polanyi, 1958) to stress the importance of knowledge that could not be reduced to rules or algorithms or even to words in a normal scientific tradition. In the history, sociology, and philosophy of science, a rich literature on 'scientific practices' has taken the inadequacy of the formal aspects of theory or explicit methods to explain the distinctive aspects of scientific knowing as its departure point. Although scientific practices may embrace everything from a knack for integrating equations to collecting botanical specimens to visualizing data, a rash of brilliant studies on experiment in the 1980s became exemplary of the new practice-centered approach. On this topic, interactions among

historians (e.g., Shapin and Schaffer, 1985; Galison, 1987; Gooding et al., 1993), philosophers (e.g., Cartwright, 1983; Hacking, 1983), and sociologists (e.g., Collins, 1985) created a discussion that blended epistemological, historical, and social analyses and inspired the next generation of historians of science.

Scientific practices more generally have emerged as autonomous forms of knowledge, no longer subsidiary to and in lockstep with theory, and have been at the center of the history of science since the mid-1990s, coinciding with the ever closer integration of the field with cultural history (Pestre, 1995). Practices have also served as an alternative way of making sense of the history of science across periods and disciplines (Pickstone, 2000). Practices usually depend crucially on local factors (including skill, material culture, values) that travel only with difficulty. This emphasis upon the locality of scientific knowledge has spawned a new set of problems: How is local science made global? In the earlier historiography, science had been assumed to be universal because nature was so. For historians of scientific practice, in contrast, further explanation is required to show the ways in which localized achievements can be made at least partially communicable among practitioners divided by geography, history, or culture (Schaffer, 1992; Galison, 1999). Sociologists of science have attacked this problem from the standpoint of 'actor networks' (Latour, 1987). In keeping with the growing interest in the circulation and communication of knowledge on a global scale, historians of science have paid increasing attention to the history of reading and publishing (Secord, 2004), the geography of scientific knowledge (Livingstone, 2003), and cross-cultural encounters (Fan, 2004; Raj, 2006; Cook, 2007; Delbourgo and Dew, 2008).

Both the rejection of presentist perspectives and the close study of scientific practices have pushed historians of science toward a more thoroughly historicist approach. Whereas their predecessors practiced anachronism openly and with conviction, on the view that past science must be understood by the lights of present science, most historians of science now writing insist upon some attempt to reconstruct the conceptual and cultural categories of historical actors. This historicism has expressed itself in two important movements in recent historiography of science: the aim to understand 'science in context,' and attempts to write histories of entities previously assumed to be transhistorical.

'Science in context' (which lent its name to a journal) thickens the connections of science with its historical place and time, as well as blurring the boundaries between factors previously regarded as either internal or external to a discipline. Indeed, one of the consequences of the studies of science in context has been to make the emergence, persistence, and occasional disappearance of such boundaries, topics of historical investigation in their own right. One of the most important of the strands of contextual history of science, because of its potentially wide application, has been the investigation of how ideas and practices of gender have shaped the modern sciences (e.g., Haraway, 1989; Jordanova, 1989; Schiebinger, 1993) and the exploration of the household and family as a site of science (e.g., Browne, 2002; Coen, 2007).

Although some critics of this embedded view have feared that context impugns scientific autonomy and therefore validity, many studies have depicted the social, technological, and economic milieu of science as resources for scientific creativity, not merely as ideological contaminants (e.g., Wise, 1989–90). Histories of supposedly transhistorical entities such as experience (Dear, 1995), truth (Shapin, 1994), and objectivity (Porter, 1995; Daston and Galison, 2007) make use of the practices of science, such as the evaluation of testimony and the making of images, to anchor these ethereal abstractions in specific historical circumstances. They are also at least indirectly indebted to the remarkable studies of Georges Canguilhem (Canguilhem, 1966 [1943]) and, especially, Michel Foucault (Foucault, 1969) that challenged the universality and permanence of fundamental modern categories like normalcy and sexuality.

In keeping with the emphasis on scientific practices, recent history of science might be briefly described as materialized and embodied. The material culture of science, ranging from the architecture of the spaces in which science is done (Rheinberger et al., 1997; Galison and Thompson, 1999) to the stuff that science works with (Klein and Spary, 2009), has shifted from the periphery to the center of historical attention. Hands-on experience with objects is no longer understood as a means to a greater end, but as a force that shapes the culture and penetrates into the metaphysics of science (Galison, 1997). Embodiment has entered the history of science through several doors: the study of the interaction of experiment and craft traditions (Smith, 2004), the investigation of the scientific persona in historical context (Lawrence and Shapin, 1998; Shortland and Yeo, 1996), and the making visible of the role of women in science (Rossiter, 1982, 1995). All of these explorations of embodiment challenge the Cartesian image of the disembodied knower, as well as the hagiography of great individuals; they aim at the reconstruction of collective identities of scientists, as well as their consequences for who was allowed to do what kind of science.

By enlarging the geography, chronology, personnel, sites, and subject matter of the history of science to encompass forms of knowledge beyond those recognized as 'scientific' by modern, Western standards, these recent approaches, informed by cultural, gender, material, and economic history, have opened up new research vistas. In one direction, historians of science are expanding into the history of knowledge. Its practitioners have queried the anachronistic assumptions that restrict the gaze of historians to institutions, actors, and genres that seem most continuous with modern ones (e.g., professors at medieval universities who write treatises but not apothecaries or goldsmiths who trade recipes) or the ethnocentric assumptions that posit a European origin of modern science that slowly diffused to other parts of the world (e.g., via Jesuit missions to China). Historians of knowledge have paid particular attention to the points at which local, lay knowledge intersected with cosmopolitan, elite science (e.g., in the exchange of natural history specimens or weather observation). In the other direction, historians of science with premodern and non-Western specialties are making common cause with historians of learning. The history of learning has also emphasized analogies between the practices of scholars and

those of scientists (e.g., between the commonplace book of the Renaissance humanist and the observation notebook of the early modern naturalist) and, more recently, the importance of studying non-Western traditions (e.g., of philological learning bound to the canonical texts of the Sanskrit Vedas or Chinese Confucianism). In contrast to historians of knowledge, who are indifferent if not hostile to attempts to draw a bright line between exoteric knowledge and esoteric science, historians of learning are deeply interested in the history of esoteric scholarly traditions and their criteria of evaluation. But they too resist the strict segregation of learning and science as anachronistic for all but the modern period.

Some have wondered whether the history of science can survive so much pushing and pulling on its object of inquiry to include knowledge and learning alongside science, not to mention the centrifugal forces of interdisciplinary approaches: in addition to its closest neighbors, history and science studies, history of science intersects with sociology, philosophy, anthropology, economics, and literary studies. Yet in this still somewhat undisciplined discipline, the reward of permeable boundaries has been a rare dialogue, ongoing and sometimes heated, among the natural sciences, social sciences, and humanities.

Abstract

New forms of activity in science are appearing rapidly, due to the interaction of the new technologies of information with new political currents. Traditional practices, structures, and assumptions in key phases of the cycle of knowledge production, including resources, persons, procedures, property, publicity, quality control, and consequences have been challenged or transformed. Political activism within science has begun, as with the boycott of Elsevier; and the rigid ideas of 'scientist' or 'the paper' are dissolving. The future is highly challenging.

Preface

It is well known that the new technologies of information are revolutionizing practice in a great variety of fields, now even including the cheap manufacture of material objects. The powers of research science in very many fields are being enhanced and even transformed. Generally these changes in technical practice take place within social and conceptual structures that were inherited from previous epochs in science. They are important new developments, but not necessarily 'new forms' of science. Here we consider the practices and structures that cause surprise and concern when they are noticed, and that have their own momentum to continue rapid change. Generally they show the effects of the new technologies of information, combined with ideas and practices imported from the wider political sphere. Since this is all happening so recently and so rapidly, we have not been able to base our analysis on a body of reflective scholarly literature. Also, we assume a general familiarity with the phenomena and the potential of the new information technologies, taking insights from the standard contemporary sources while discounting their more speculative conclusions. Because of these constraints, this article will be more in the form of an analysis with examples, rather than a review and synthesis of literature. This is not a standard form for an encyclopedia, but the unusual subject matter requires it.

Historical Background

About a half century ago, there was awareness among scientists that things had changed. The transition was captured in the seminal book *Little Science*, *Big Science*, by Derek Price (1963), which reflected on the rapid expansion of science, particularly in the USA, and its harnessing to production and war as in the Manhattan Project. Over the following decades, this new situation became the occasion for many reflections, along with new lines of debate, which developed gradually. The current situation of science is a very rapid change. Attitudes and activities that were unthinkable only a decade ago are now well established. Who would have imagined that eminent scientists would organize a boycott of a leading scientific publisher? But that is what the leading mathematician, Timothy Gowers (2012), did to Elsevier, with the support of thousands, with the slogan 'Academic Spring.'

The changing self-consciousness of scientists during that previous period is a reminder that, in the sociotechnical system of science, the intellectual and material aspects of the system are deeply implicated in one another. As we move, perhaps headlong, into a new set of material and the conceptual relationships, it is helpful to gain perspective by going further back than 'big science.' Since it is the means of communication that are most obviously being transformed by 'digital' media, we can recall the impact on science of printing during the Renaissance. This enabled the diffusion of knowledge in obvious ways, feeding its growth. The publication of a book enabled a practitioner to advertise his talents, and thereby to obtain the best patronage available on the market. Agricola, Biringuccio, and Vesalius are great examples. Galileo exploited this technique, parlaying his *Sidereus Nuncius* first into a pay rise in Venice, and then to a coveted position as 'Chief Mathematician and Philosopher' at the Medici's court back home in Florence.

By the end of the sixteenth century, the great national industries of conquest, war, and royal display gave employment as never before to practitioners with mathematical skills. The traditional status barriers between 'liberal' knowledge and 'mechanical' practice were lowered, for a few generations at least. Simon Stevin was a genius who worked as a practitioner but showed philosophical ambitions, while Galileo was just on the other side of the divide and determined to stay there. William Gilbert was the first to unify 'philosophy' and experimentation in his *de Magnete*; there he also rigorously reported which experiments worked and which did not. Bacon's rhetoric about 'torturing nature' became a successful practice among the 'experimental philosophers,' most notably in the great English school with Boyle, Hooke, and Newton. By the eighteenth century, the union of theory and practice was fully established, and philosophers in the 'highland zone' of Britain combined ideology and improvement (with profit where obtainable) to great effect.

As the powers of technology grew through the nineteenth century, scientists (who then got the title) could study natural powers in artificially controlled situations, notably in relation to electricity and magnetism but also to both old and novel chemical substances. The cross-fertilization of heavy industry with mission-oriented scientific research was established, first in Germany (starting with Liebig) and then elsewhere, notably

 http://dx.doi.org/10.1016/B978-0-08-097086-8.85027-8

in the USA in the great labs dominated by such iconic inventors as Edison and Steinmetz, along with the quasi-magical Tesla. During the same period, the university system was forced to graft research onto its traditional roles of teaching and socializing the young elite. One later product of this merger was a collective amnesia among scientists and scholars about the role of such organized, industrialized research and development during the 'little science' period, a misunderstanding that led to much confusion when 'big science' arrived in full force.

In the epoch that was inaugurated by the Manhattan Project and is now just ending, science became 'industrialized' in several respects: in overall size, in scale of individual enterprises, and in its ever closer relations with industry. It also became 'incorporated' (Rose and Rose, 1969), that is, involved in a variety of ways in the affairs of the state, far beyond the traditional connection with warfare. Somewhat naively, scientists believed that they were being asked to speak 'truth to power,' when their clients frequently wanted 'policy-based evidence.' Traditional stable subject-specialty research has been displaced by 'Mode 2' (Gibbons et al., 1994), in which scientists are fungible units of production, to be deployed or discarded as the needs of mission-oriented projects dictate. In its relations to the broader society, the manipulations and distortions of research that are now familiar in connection with profit-making industry (such as research on tobacco, food, and pharmaceuticals *inter alia*) are mirrored in the less notorious, but equally important practices of ministries and agencies. The 'Gemeinschaft' research communities of yesteryear survive only on the margins, although Steven Shapin has argued that they are being recreated out of necessity in the fast-moving fields of innovative entrepreneurial science (Shapin, 2008).

Structures of Scientific Activity

Having very briefly reviewed the historical background, we can now sketch the relevant structures of scientific activity. Then we will be equipped to understand the influence of the new technologies on the new forms of scientific practice. It is now commonly appreciated that the old picture of 'the scientist' making a discovery and then turning it over to 'society' is very radically oversimplified. First, the possible motivations for engaging in, or supporting, research are varied. Aside from the traditional 'curiosity,' there is also 'mission-oriented,' 'mandated,' 'regulatory,' and (we must now add) 'critical' motivation. The relations with broader society, the internal social structure, and the ruling criteria of adequacy and value, all depend on such initial motivation. By appreciating the basic variety in the production systems of scientific knowledge, we can then consider the cycle of activities through which knowledge production goes.

The initial motivation is but the first step in a multiphased cycle. We might call this first step the 'issue,' as that is where policy-relevant science gets its start. Next comes 'policy,' which expresses the hoped-for solution and defines the parameters of the design of the project. This is most easily seen in research on risks; for 'the risk' is itself always complex, and simplifying design choices must be made on the subjects to be studied and on the nature of the hazard they experience (e.g., adults, children, pregnant mothers, and chronic or acute doses, average or peak exposure, etc.). And 'problem,' giving greater specificity to the inquiry, perhaps stating a statistical hypothesis to be tested, comes soon after. Quite essential at this early stage are 'resources.' Since science does not operate in an ideal universe, this issue inevitably brings in politics, in the classic sense of 'who gets what, how, and why.' Politics also enters with 'persons.' Whenever policy is at stake, this can be quite crucial; even if scientists all have integrity, they act rather like judges, and this does not prevent them from leaning this way or that when confronted with uncertainty and value conflicts. This step has become problematic in several ways recently, and is closely related to the new politics of science. Then come 'procedures,' which are necessary because research is never straightforward, but is rather the study of the 'proxies' for the conceptual things and events that are of concern. In all such cases, there are numerous standards and conventions defining good practice, which are designed and implemented for avoiding the known pitfalls of data creation, interpretation, and inference. A high-quality scientific paper contains dense descriptions of those procedures, thereby assuring its readers that its results are robust. At the core of the investigation there is 'production,' where someone interacts with equipment (or respondents) to obtain the primary data, which will be the intended representatives of the proxies for the defined objects of inquiry. Out of this comes 'product,' realized in an 'inscription' which may function as 'paper,' report, or patent application. Beyond that there is 'property,' which also includes control over 'publicity.' It was once assumed that the public sharing of results was definitional of science, as opposed to the proprietary control over invention. But it has recently emerged that the publication of data is by no means universal in spite of being formally required by many funders and journals. Of course, when data are withheld it is impossible to operate Merton's norms of 'communalism' and 'organized skepticism,' which had been accepted as fundamental to 'pure' science. Near the end of the cycle are the traditional 'applications' and the recently recognized 'consequences.' These are now recognized as critical to the inquiry, and will include the 'bads,' or 'unintended consequences' that arise from the applications of scientific results. The relevant sciences here are almost polar opposite in character from the traditional lab disciplines. For the problems are usually 'postnormal' (Funtowicz and Ravetz, 1993), in having high uncertainties and high decision stakes, politicized debates over the assignment of burdens of proof, plus imbalances of prestige and of conventional institutional funding, with whistle-blowers sometimes being as important as researchers, and open conflict breaking out between pressure groups and vested interests.

Such a cycle helps to explain the complexity and confusion that attends debates when science is involved with policy. Without a shared awareness of the different phases of the production cycle, debates can wander inconclusively through a maze of topics. Moreover, each of those phases of the production cycle has its own 'quality control cycle.' This feature establishes the true complexity of the process. For whenever there is an action conducted within an organized system, it will be subject to 'control' for its quality. This operation will include particular agents, operating particular criteria and adopting particular procedures for controlling and evaluating quality. Whenever a regulatory body comes to public notice, it will be seen that it has these elements: agents, criteria, and procedures.

Moreover, the control cycle itself is subject to control cycles. Let this seem paradoxical, we recall the Latin epigram, "Quis custodiet ipsos custodes?" – who guards the guardians? Sheila Jasanoff first called attention to this phenomenon in science advice in her pioneering work *The Fifth Branch* (1990). Such an iteration is familiar in connection with the administration of justice, with a sequence of courts of appeal, right up to some highest court from which some political influence cannot be excluded. More to our present concerns, as our companion article in this Encyclopedia argues (*see* Peer Review and Quality Control), quality has replaced truth as the effective guiding principle for science. The 'quis custodiet' iteration is a reminder that quality cannot be maintained by enforcement alone. It requires an ethical commitment, one that must be seen to be practiced at the top of any institution. In its absence, corruption, and vacuous research are sure to follow. We have previously remarked on the paradox that the successful production of objective scientific knowledge depends critically on this subjective ethical commitment (Ravetz, 1971: Chapter 11).

Persons

We can now look at the production cycle of scientific knowledge in greater detail, identifying important points of novelty. In recent decades there has been a growing recognition that policy-relevant science is done better if the early stages, as issues and even problems, draw on broader experience than that of politicians, science advisors, and experts. Some time ago the term 'extended peer community' was coined (Funtowicz and Ravetz, 1993) and, since then, under many different names, the involvement of citizens has become increasingly accepted as desirable and useful. The obvious constitutional problems presented by these exercises in 'participation' have somehow not proved insuperable. Particularly on public health issues, broader participation in problem definition has become established, starting with the campaigns by AIDS activists (Epstein, 1996). Such developments have diluted the original force of the very idea of 'scientists,' as the sorts of persons involved in the research cycle become ever broader. In conventional scientific research, there is a long continuous tradition of amateurs making contributions, but more recently they had been relegated to the role of lower-status assistants. Such were the neglected sisters of astronomers in the past, and the numerous bird watchers in the present. That approach to broader involvement is the least threatening to established orders, and it motivated the pioneering 'Galaxy Zoo.' In that case, the groups of amateurs even suggested topics for closer investigation. But a more active involvement is developing all the time, such as in the Web sites for folding of molecules, and even for solving difficult mathematical problems. In another direction, there is 'garage biology,' still very small and marginal but with great potential. Now Web sites, such as Petridish.org (available at: www.petridish.org, accessed 29.08.13.), are being created to serve scientists who want to bypass the established channels for resources; although innocent in intent, such developments inevitably will affect the politics of resource distribution in science. More immediately serious is the parallel universe of the informally trained hackers of information technology (IT), including everything from pranksters and libertarians over to gangsters and state agents. As a result of all such developments, the status of 'scientist' is being progressively diluted; one no longer needs to have gone through the lengthy process of selection and training, culminating in a PhD at the top of the cleverness pyramid, in order to be accepted as a member of a recognized knowledge-producing community. The status of 'expert,' someone who has authority to solve particular problems on the basis of his specialized scientific training, is being eroded even more rapidly. With the growing contestation of science-policy issues (ranging from nuclear power to vaccination), along with the increasing use of crowd-sourcing for decisions, expertise is becoming a beleaguered role.

A most important recent development has been the loss of the presumption of Mertonian 'disinterestedness' in someone certified as a scientist. Authors of papers are now routinely required to declare any potential conflicts of interest, on the assumption that these are relevant to their claims. Also, research done with industrial support has its quality discounted, on the basis of presumed bias that is supported by surveys of outcomes (Lundh et al., 2012), to the point where some firms are abandoning public research. Since a very large proportion of ostensibly scientific research has been supported by industry and the military, this new awareness can destabilize long-established patterns.

Procedures

A similar process of change, variously seen as erosion or democratization, affects procedures. For a long time, there was a common belief in a scientific method, those procedures whereby science unerringly produced the correct answers to its problems. It was the job of history of science to show that science always got it right, and of the philosophy of science to show how this was so. With the rise of uncertainty, first in theoretical physics, and then of complexity in knowledge and policy, this motivating faith gradually lost plausibility. The inability to specify a method that is not logically fallacious has contributed to the difficulty. Popper's philosophy of 'falsificationism,' so valuable as a moral injunction, turned out to be vacuous for the construction of knowledge. Once scientific practice is dominated by statistics, there is no question of 'truth' as traditionally understood, for the results depend on counterintuitive and obscure reasonings about null hypotheses and confidence limits. Even the standard statistical techniques, applied unreflectively in all of 'normal' science, have been severely criticized, as by Ziliak and McCloskey (2008). As for models, which absorb ever more research effort in all fields, and squeeze out the more expensive and time-consuming traditional methodologies, the best that can be said is the classic line 'all models are wrong; some are useful.' The 'quis custodiet' iterative principle applies most strongly to procedures. The products of inquiry are subjected to direct testing, however imperfect, but the testing of procedures is of an entirely different order of complexity and difficulty. It is not surprising that one author (Ioannides, 2005) has found multiple examples of shoddy and low-grade work leading to unreliable and unworthy science. It is impossible to say how much of this depressing development is actually new;

certainly, poor quality science has always been with us, as has been noted in the past (Ravetz, 1971: Chapter 10). But there does seem to be a much-heightened awareness of these problems within scientific communities, and this could simultaneously have the opposing effects of stimulating reform while also reinforcing cynicism.

Property

In the previous epoch, the social relations of property had not been changing with great rapidity; there was a steady displacement of the traditional 'public knowledge' by what we might call 'corporate know-how.' However, there has been a recent recognition of a deeply paradoxical situation in the management of intellectual property. In the new emerging technologies, notably in nanotechnology, there is a confused mixture of systems of intellectual property. Much work is done on public funds and in the public domain, while much else is proprietary. And this division is not restricted to results, but also to the ancillary information that is essential for the research. There has been a recent warning that the progress of the field is being seriously impaired by the thickets of property rights that surround the various bits of knowledge and technique that are necessary for research. Thus, right here in science we have an example of Marx's description of the replacement of one mode of production by another in the *Communist Manifesto*: "the feudal relations of property became no longer compatible with the already developed productive forces; they became so many fetters. They had to be burst asunder; they were burst asunder." We can see a sort of parallel in science, whereby the small-scale semiindependent handicraft researcher has recently been displaced by the knowledge-worker in industrialized, or 'Mode 2,' science. Marx saw the boom-and-bust cycle of modern industrial capitalism as a sign of a similar deep systemic crisis for itself, and imagined that the revolutionary proletariat would soon step in. That was not to be, at least on his timescale. However, it is now widely recognized that in order to maintain the momentum of scientific innovation, the self-strangling hybrid system of intellectual property requires supplanting by the new social relations of production, characterized as 'open source' or 'creative commons' on the example of the Intellectual Property (IP) systems of some key Information Technology (IT) industries (Igoe and Mota, 2011; Brooks, 2012). Without indulging in rhetoric about 'bursting asunder' the fetters of the IP rights enshrined in patents, we can see that deep change is inevitable and already underway. Even Big Pharma has taken the point, as with the Gates Foundation on Tuberculosis, and GlaxoSmithKline in its Tres Cantos Open Lab Foundation (Nathan, 2012). Under these new circumstances, the 'gravediggers of (scientific) capitalism' will not be Marx's proletarians 'with nothing to lose but their chains,' but rather Clay Shirky's possessors of 'cognitive surplus, spreading creativity, and generosity in a connected age' of digital knowledge (2010).

Publicity

Innovation is even more rapid in the phase of publicity, which is after all the lifeblood of science and consisting of information. What is significant for the self-consciousness of science is the sudden discovery that there actually is an urgent and deeply problematic political economy of publicity. Previously accepted as the unproblematic norm with occasional deviations, publicity has rapidly become the focus of concern and even of grievance. This issue, even more than property, may become the lever whereby the idealistic ethical assumptions of 'little science' come to be seen rather like liberty in the political sphere, not to be assumed but requiring vigilance and struggle for their preservation. The distinguished mathematician invoking Tahrir Square against the publisher Elsevier may be iconic for the emerging contestations over public knowledge in science. The issue of secrecy and publicity emerged almost incidentally in the rather troubled evolution of the well-intentioned science of global warming. Leading scientists were affronted by demands for their data made by unqualified critical outsiders. Eventually it required freedom of information procedures against individuals and institutions, in the USA and UK, to unlock data that had been produced on public funds. The critics could not be isolated and neutralized, as in previous debates (notably over bovine spongiform encephalopathy (BSE) or Mad cow disease), as they formed an 'extended peer community' in the 'blogosphere,' the most popular site enjoying both a readership in the millions and prizes for quality (see www.wattsupwiththat.com, accessed 30.08.13). The issue of secrecy of publicly funded data became so urgent that there was an official response from the Royal Society of London, in the form of a working party chaired by Professor Geoffrey Boulton (Royal Society Policy Centre, 2012). Its report strongly recommended procedures for insuring that such data should be public, although it did not extend its recommendations to the computer codes whereby such raw data were converted to usable information. In the ensuing discussion, it emerged that many rules for data publicity already existed, but that they were generally ignored by all parties to the publication process. The awareness of the problem soon extended from research data to those used in the regulatory process. It became realized that public regulators commonly make decisions based on secret data. In the atmosphere of mutual suspicion, the principle was invoked, "if they are hiding something, they must have something to hide." Accusations of possible malpractice by leading pharmaceutical companies, and of serious incompetence in data management by European regulators, have been made in the most authoritative quarters (Goldacre et al., 2012). It is only natural that the issues of publicity and quality should become entangled in this way. The most effective way to seize the moral high ground in a science-policy debate is to call for transparency and openness, thereby invoking the traditional norms of science combined with the modern imperatives of participatory democracy.

On another front, ethical issues in fairness to access to information have suddenly become urgent. Publication is not free, nor even particularly cheap. How are the publishers to be recompensed? The problems of cost and recompense in the digital age that had already afflicted the creative industries have suddenly arrived in science. Previous cozy arrangements whereby academic libraries subsidized publications through their subscriptions (and also provided a hefty profit) no longer go unchallenged. Also, it is suddenly realized that there are many worthy people out there who need access to nominally public

information, and who cannot or even should not pay large fees for the privilege of sampling it. All that information waiting there on the Internet, or cloud, turns out to be free only for those who are subsidized by an institutional library that can afford the fees for an extensive license. Without membership of such a wealthy institution, the would-be researcher must produce significant payments for each item of essential information in the nominally 'public knowledge' sector, even for research to which they have contributed through their taxes. The publishers are now suddenly subjected to outrage, as academics accuse them of getting all their editorial services for free and then securing superprofits through their quasi-monopoly control of high-prestige outlets. The whole social system of scientific publication, which had been a model of success for generations, performing a great variety of functions (diffusion, archive, quality control, evaluation, and allocation of resources) is suddenly required to rethink itself. And this crisis occurs in conjunction with the arrival of the new technologies of publicity, which threaten the monopoly of paper publication with all its very useful structures and constraints. We should not underestimate the severity of this challenge to the social institution of science as we have known it.

In science, as in other areas of knowledge production, the new technologies dissolve previous boundaries. Previously the forms of publicity were atomized, in harmony with the production process and the conceptual objects. That is, 'the paper' was realized in a congealed text, printed in multiple identical copies on paper. It was the product of a defined original study by 'an author' (or, in industrialized conditions, a defined collection of authors). That study had its own distinct closed cycle from inception to completion, as reported in the paper. Even quality control was atomized, with anonymous reviewers reporting to a single editor, determining the fate of 'the paper.' The social conditions of industrialized knowledge production, particularly in relation to the reward system, which determined career opportunities, militated against leisurely investigations, as of the traditional natural history or even the reflective natural philosophy characteristic of 'gentleman-amateur' science. Accordingly, the atomized quick-returns project has come to dominate all aspects of the cycle. A parallel development in what can be called the practical ontology of science fitted in with this style: the effort was to study simple, or simplified, systems, using conceptual objects and tools, usually statistical and mathematical, which enabled simple judgments to be made. Thus among biologists the emphasis became to focus on the smallest scales possible, from biochemistry down to genetics; whole, complex systems were deemed incapable of scientific study, as indeed they were under this definition of science. The process can be seen in its extreme parodic form in mainstream economics, where abstract mathematical models of the decisions of mythical atomic actors served to reinforce the politically driven assumptions of the discipline. In strong contrast, thanks to digital publication, the ongoing inquiry can now be a focus of a continuous flow of communal dialogue and development, in which there may be a temporary crystallization of a 'product' as a matter of convenience. Leading journals in all fields now run blogs on their Web sites, providing alternate and informal channels of communication and dialogue. Thus, all the previous atomized social structures of quality, social control, publicity and access, and by extension the practical ontology of science, are thrown into confusion. Along with 'interdisciplinarity,' complexity is now becoming a keyword in all sciences relevant to policy. We see here how all the different aspects of the production of scientific knowledge are mutually implicated in this transformation; starting with publicity, we have just shown how research practice and even practical ontology are affected.

Quality Control

The effects of the new technologies on the quality control cycle are, if anything, even more dramatic. Traditionally, the quality assurance systems of science were run largely informally and largely confidentially. The mere fact of publication of a paper was taken to be its stamp of quality. All the processes of criticism and improvement were kept secret; the atomic unit of established knowledge embodied in the paper carried no penumbra of uncertainty or quality. Of course this system generally performed well, but it is highly sensitive to the quality of the quality-guardians and even more so of theirs. It is all too easy for peer review to degenerate into 'pal review.' For quite some time, the deficiencies of the peer-review system have been aired and considered, and the conclusion has always been that, rather like democracy, it is the worst possible system except for all the others. The technology of information contributed to this stasis: the sheer bulk of papers containing reviews, reports, and revisions for a single publication would be inconvenient and expensive to make available for a wider scrutiny. Opening the files of documents on all publications would be impossible. But with the new technologies of information, we have new devices. Perhaps, the most revolutionary of all the 'apps' recently invented is the Wikipedia. For, as Wikipedia itself has shown, with Wiki all the editorial processes can be both convenient and transparent. On Wikipedia, every article appears with a sort of pedigree, and cocreators are invited in to contribute to the public quality assurance process. Of course the process can be, and often is, abused, but then the abuses are usually spotted quickly and a lively open debate ensues. In many ways, this approach is being incorporated into research science. What had hitherto been a remarkably closed institution, with little public scrutiny of its internal politics, and hardly any investigative journalism (with Mae-Wan Ho and Jonathan Latham providing the main exceptions), is now starting to be opened up. We can hope that the transition to effective 'openness and transparency' in the governance of science, starting with quality assurance, will be smooth; but it must come, and will come.

Consequences

Near the end of the cycle is consequences. Traditionally, it had been assumed that this had nothing to do with scientific discovery. The consequences of science were assumed to be essentially good and overwhelmingly benign in practice, and so the scientist could, with a good conscience, turn over his products to society for development and control. During the twentieth century, first in war and then in the fields of safety, health, and environment, consequences obtruded with increasing salience. A natural reaction was to bring all those

issues under scientific control, with 'risk' becoming the dominant concept, displacing 'safety' and 'danger' in scientific discourse. This was defined as the product of the quantified probability of harm (always assuming that these had precise measures). There was even an ethical application: if a novel risk was no greater, quantitatively, than one already accepted, then only those who were misguided or malevolent would reject the new risk. Such analyses were applied in the early debates over civil nuclear power, and were discredited, along with the industry itself, by the disasters in the USA and USSR. By the end of the century, the inescapable presence of risk (still not 'danger'), along with its characteristic politics, was analyzed in the classic work *The Risk Society* (Beck, 1992). Now the issue of consequences is recognized as crucial in policy debates on new technologies, be they genetically manipulated crops or nanotechnology, as well as in broader policy debates, such as those on climate change resulting from industrialization. However, the science that is universally accepted as necessary finds it very hard to develop strength that is adequate to its tasks.

To understand this imbalance, we can see this new task as dealing with the bads, rather than with the goods that are the traditional goals of science. These problems will usually be 'postnormal' in having significant uncertainties and decision stakes. Even when there is little scientific uncertainty, vested interests can delay action by manipulating all relevant processes. The US tobacco industry, 'manufacturing doubt,' is the classic case; more are to be found in the seminal work *Late Lessons from Early Warnings* (European Environment Agency, 2002). Then, normally the bads are unintended consequences of mainstream science/technology done in the standard mainstream atomized way. For their study, the relevant fields will usually be marginal, and weak institutionally and politically, and perhaps even weak scientifically as well. Without any conscious intention, the rules of the mainstream scientific game are rigged against those who would pursue the science of bads. All this is changing rapidly under the new conditions of scientific practice. First, there is a structural asymmetry in the opposing sides of any debate on possible bads. The proposers are concentrated and organized, institutionally and personally. The opposition is typically a coalition of scattered aggrieved citizens joined up with underfunded NGOs. But just as the printing press and the rotary duplicating machine facilitated protest in earlier ages, the mobile phones and social media do so now. Also, since the protection of bads involves secrecy, the powers of new information technology to penetrate records and expose secrets redress imbalances of knowledge and hence of power. Further, in modern society there are many protestors with education and applicable skills, so the traditional class divides are dissolved. The technique of 'Community-Based Audit,' where the data, methods, and paradigms of proponents of developments are scientifically scrutinized by scientist-citizens and citizen-scientists working together as a preliminary to dialogue, is a valuable contribution to the science of bads (Tattersall, 2010). We will know that science has genuinely entered its new epoch, when the science of bads becomes recognized as a subject worthy of being taught as part of a liberal education in science. A good start has been made in the announcement of the 'Oxford Principles' for responsibility in the governance of geoengineering research (Oxford Geoengineering Programme, 2012). They could provide the same service for the science of bads, that the 'Mertonian norms' for scientific integrity have done for traditional research.

A Problematic Case

A recent case encapsulates all these issues in consequences, or the science of bads, at the intersection of state regulation, populist politics, and information technology. It started with a thoroughly traditional debate on bads, in this case the claimed possible harmful effects of a strain of genetically modified (GM) maize, which is intended for use as animal feed in the European Union (EU). Although it had been cleared by the European Food Safety Agency (EFSA), powerful forces in France were opposed to it, and they derived support from a scientist at Caen named Séralini, whose tests, he claimed, showed danger (Butler, 2012). He had completed a new series of lengthy feeding tests, and had ambushed the opposition in its publication. The respectable scientific journal publishing the paper gave no advance notice to journalists, and the publication was accompanied by a film! In the row that followed, the critical statement by the EFSA was published on their Web site, and nothing could prevent the scientist from stating his rebuttal, at length, in the commentary section. Among the many criticisms of his work made by reputable scientists was one that alleged that he had not released his primary data. He promptly converted this into a challenge to the EFSA to release the data on whose basis they had decided that the product was safe. Why indeed were they so secretive? The EFSA soon called his bluff, launching an initiative for publication of data that had actually been planned for some time (EFSA, 2013). As ever-more authoritative criticisms piled in, something entirely different happened. This was a proposal by a group of anti-GM scientists in Russia, to perform a 'rat reality show' (Sharoykina, 2012). This would be a year-long Internet–TV 24/7 real-time feeding experiment to test whether GM products are harmful. Feeding procedures would be appropriately blinded, and there would be supervision by a committee including all tendencies in the debate. The sponsors claimed that in this way the public could have a trustworthy experiment to witness, and could then draw their own conclusions on the safety of GM products. If the group cannot obtain resources for the show through orthodox channels, they plan to crowd-source the funding. There was no immediate response to this proposal. Is it a stunt? An opening to scientific demagoguery? Or a harbinger of a real 'science by the people'? Should we now start to speak of Zapatista science? For now, there is no way to know. But now that political power within science is diffused and perhaps also confused, the future is not foreclosed.

Citizen Science – an Emerging New Form of Science?

It is useful to draw together the threads of the previous discussions of citizens' activity in science, and to consider whether this is actually an embryonic new form of science. If so it would be a successor to the earlier phases, going back from industrialized/incorporated/academic to practitioner/gentleman-amateur. This new practice is based on a rapidly growing technology of social communication, has precedents in the 'creative commons' culture in IT, and draws support from

a great variety of institutions. Its own varieties of practice in relation to mainstream science have been described as: contribution, collaboration, and cocreation. The enormous differences in social organization between these roles are obvious. It can provide support for mainstream research, opportunities for individual creativity, and also means for opposition and protest. In this latter role, it can connect to the radical social-media movements, focused on issues of environmental and broader social justice. Is it developing a consciousness of itself and for itself, distinct from other forms of scientific practice? It is still too early to tell, and so far there is no sign of the internal conflicts that would inevitably accompany any attempt at self-definition. As it grows, it will need to establish procedures for quality-assurance, for excluding cranks and malefactors, and for relating to 'mainstream' science. Whatever happens, it is highly likely that in the next edition of this Encyclopedia, 'citizen science' will not be an afterthought.

Conclusion

We must keep a sense of perspective. All these developments in digital-age science, especially those on the populist fringe, are very much on the margin. The vast majority of scientific work is done just as it has been, in large labs with traditional structures of quality control. The immediate problems facing the scientific communities, such as deceleration of growth, shifting of activity to the East, disentangling the publications system, and shoring up the quality assurance system, continue to require attention from all concerned. Creativity flourishes, in a spate of new inventions as well as in debates on the scientific problems bordering philosophy and theology. But this article is devoted to 'new forms of science,' and so long as they are new they will by definition be on the margins, uncertain, indeed speculative in their future course. We might adopt the title of a recent prophetic book, *Science 3.0* (Miedema, 2012), as the motto for our journey into this unknown and challenging future.

Abstract

'Public engagement with science' evokes a series of long-standing issues concerning the relationship between members of the public (or citizens) and matters of technical expertise. However, each of the terms 'public,' 'engagement,' and 'science' is open to question, and to empirical investigation regarding their definition in institutional practice. Science and technology studies scholars have been especially active in challenging prevailing policy assumptions in this area and in considering how science–public relations might be reinterpreted and reconstructed. This article presents some of the key social scientific contributions to this developing area of discussion and practice.

Introduction

Considered in general terms, it might seem that there is little new in the relationship between expert knowledge and wider publics. As Dorothy Nelkin expressed the central political dilemma: "The complexity of public decisions seems to require highly specialized and esoteric knowledge, and those who control this knowledge have considerable power. Yet democratic ideology suggests that people must be able to influence policy decisions that affect their lives" (Nelkin, 1975, p. 37). Writing in the mid-1970s, Nelkin observed that controversy and public dispute were often associated with 'technologies of speed and power' (airports, power-generating facilities, highways, dams), creating significant challenges with regard to the public role of science. By the beginning of the new century, the issues of concern had shifted away (at least primarily) from 'speed and power' and toward the biological sciences (stem cell research, nanotechnology, synthetic biology, questions of food and food safety) (Bauer and Howard, 2012). However, many of the themes raised by Nelkin remain recognizable today: the ambivalent role of science in controversial policy arenas, the variable impact of expertise on political decision making, the at-times problematic relationship between expert evaluation and citizen action.

Although partly anticipated by Nelkin (1977), since that time – and especially since the 1990s – a public rhetoric of 'engagement' around science and technology has developed in many countries, a rhetoric that has been specifically embodied in a series of 'engagement' initiatives (including national debates, consultation exercises, consensus conferences, and the involvement of 'lay' members on scientific advisory committees). To offer one much-discussed example of this 'politics of talk' (Irwin, 2006), the UK in 2003 witnessed a large-scale public consultation over the commercial growing of genetically modified (GM) crops (Horlick-Jones et al., 2007). Other notable cases can be identified, both within European nations (for example, Sweden, Denmark, The Netherlands) (Hagendijk and Irwin, 2006) and more globally (including initiatives in the USA, Canada, New Zealand, and Australia) (see for example, Guston, 1999). In parallel – and at times in close relationship – with such initiatives, social scientists (including science and technology studies (STS) scholars) have developed empirical analyses of these developments, generating also a series of analytical constructs and case-based commentaries. Indeed, one characteristic of this field of practice and scholarship has been that terms entirely or partially developed by social scientists (for example, the deficit model, upstream engagement, citizen science) have influenced (and in turn been influenced by) the language of practice.

Seen from the perspective of STS, the very phrase 'public engagement with science' (PES) raises a series of demanding questions and challenges. How is the 'public' to be defined and what should be its relationship to matters of scientific and technological change? What is meant by 'engagement' in this context? What form should this take, and does the phrase imply that wider society can ever be 'disengaged' from scientific and technological development? It is also a central commitment of STS scholarship that 'science' (like 'the public') should be seen as plural, not singular, and as overlapping with other domains of social, technical, and material practice (as expressed in terms such as 'techno-science' or 'sociotechnical networks'). In line with this problematization of 'public,' 'engagement,' and 'science,' many academic studies have been sharply critical of institutional activities in this area, viewing specific initiatives very often as centralized and highly constrained attempts to 'capture' public opinions without any substantial commitment to the broader principle (or potential) of dialogue and engagement. Nevertheless, the issue of PES raises important questions about the relationship between science, governance, and political values, and especially about that between the larger publics and relevant scientific innovations.

This article does not set out to summarize practical experience within PES, although, given the nature of this field, some sense of the topic will necessarily be provided. Instead, it considers specific social scientific contributions to this area of investigation and debate, and covers some of the key concepts and areas of discussion developed especially by STS scholars.

The 'Deficit Model'

It is important to note that current social scientific discussions of PES have to a large degree evolved from an earlier (but still extant) series of debates and practical activities concerned with the 'public understanding of science' – a term which continues

to be employed among, for example, British science policy-makers. Specifically, a Royal Society report on that topic (1985) made an influential case for the 'better public understanding of science' but also became a particular focus for social scientific criticism. Thus, one of the major contributions from the 1990s onward by STS scholars has been to challenge the assumptions about technical knowledge made by key societal institutions (for example, government agencies and industry) when 'engaging' with larger publics. One major social scientific input has been to identify 'deficit' assumptions within much institutional policy and practice in this area. At the heart of the 'deficit model' (or 'theory') of science–public relations is the notion that 'the facts' relating to a controversial area of science and technology can be separated from political, social, and ethical matters.

Put very broadly, the institutional tendency has been to view public engagement (or 'understanding') as essentially a matter of getting these 'facts' across to public groups, which are viewed as uninformed, ignorant, or emotional in the face of new scientific developments. In the context of the 1990s, the critique of, for example, the nuclear industry was that it presented opponents of civil nuclear power as operating within a cognitive 'deficit' coupled with 'fear' or 'dread.' In line with this assumption, external criticism of the industry was defined primarily as a matter of misunderstanding the scientific case for nuclear power. The challenge for the industry was therefore to educate and inform these 'deficit' publics. While such an approach may have appealed to the developers and promoters of new science and technology, the consequence was (and continues to be) that such institutions failed to consider the possibly legitimate issues raised by critical social groups (in this case antinuclear organizations) as well as their own role in provoking public concerns. The deficit model functions therefore both to problematize critical publics and to insulate institutions from societal challenges, questions, and concerns.

While critiques of the deficit model were developed in the 1990s (see for example, Irwin and Wynne, 1996) – and have subsequently become part of the vocabulary of many engagement practitioners (including in government) – this remains a lingering issue within engagement activities. Certainly, the accusation that specific initiatives are about 'deficit rather than dialogue' has been recurrent since that period. On the one hand, the deficit model serves as a reminder that what is presented as dialogue may offer no more than one-way (or 'top-down') communication, with the wider publics considered as passive recipients rather than active partners in mutual deliberation. On the other, accusations about one or another 'deficit' should not obstruct the broader point that deficiencies of understanding are unavoidable on all sides, and indeed serve as a powerful motivation for dialogue and engagement. From a broad STS perspective, the issue may be less one of 'removing' deficits than of challenging assumptions about what should count as the relevant 'facts' within engagement exercises.

Citizen Science and the 'Knowledgeable Publics'

In this context of problematic science–public–institutional relations, it was perhaps inevitable that social scientists from the 1990s onward would point to domains in which the larger publics could be presented, not simply as recipients of knowledge and information (as in the 'deficit' formulation), but also as active creators of expert knowledge who possess distinctive understanding. In his classic study of nuclear fallout following the Chernobyl disaster, Brian Wynne (1996) observes how a group of sheep farmers demonstrated substantial knowledge of local environmental conditions and animal behavior, especially when compared with the putative 'experts.' The contrast here is between generalized models of (for example) ground contamination – as developed by 'laboratory science' – and the intimate knowledge of specific conditions built up by the farmers in question. Significantly also, the knowledge possessed by the sheep farmers did not fall within one epistemological or disciplinary category, but brought together shared experience, direct observation (often over a very long period), and personal judgments as to the credibility of competing claims to 'know best' (with the government scientists losing credibility as their ignorance of local farming conditions became steadily more evident). Linking with other treatments of 'indigenous' or 'local' knowledge, STS scholars such as Wynne thereby indicate that so-called experts may have as much to learn as the 'lay' interlocutors with whom they seek to 'communicate' within such contexts. However, 'citizen science' (Irwin, 1995) in this sense does not represent an alternative to 'conventional science' – nor does it claim to have a 'better' cognitive understanding of specific conditions. The point instead is that all knowledge claims are 'contextual' in character – including those claims that draw upon standardized protocols and methods of blind peer review.

Beyond STS, 'citizen science' has become a popular term to describe programs in which members of the public who lack formal scientific training engage in scientific projects. Often this takes the form of public participation in large-scale data collection: for example, surveys of garden birds and other species, astronomical observations, and studies of pollution and public health. Representing a form of 'crowd-sourcing,' citizen science in this sense offers a way in which groups of attentive citizens can augment and extend scientific activities, while also gaining a sense of 'engagement' with science. Although this form of 'citizen science' may not have a primarily political or dispute-based focus, it can certainly have policy-related implications, such as when local ornithologists observe changing patterns of bird migration that may in turn have consequences for the general understanding of climate change. Perhaps the main difference between the STS discussion of 'knowledgeable publics' and the more common idea of 'citizen science' is that the latter suggests a greater willingness to work within the epistemological boundaries of science whereas the former explicitly brings social and political judgments into the definition of 'knowledge' (as when the sheep farmers in question explicitly challenge the trustworthiness of externally appointed experts). In practice, however, there may be considerable blurring of these distinctions. Meanwhile, the concept of public knowledgeability and crowd-sourced science suggests perspectives on engagement that take us substantially beyond the restricted framework of the deficit model.

Engagement and the 'Crisis of Trust'

Although the United Kingdom was not an early starter in terms of public discussion, participation, and consultation around science and technology (with countries such as the USA, The Netherlands, and Denmark running substantially ahead during the 1970s), experience in that country through the 1990s, and the institutional lessons drawn from this experience, have been broadly influential both in terms of STS scholarship and international policy-making. Certainly, the UK in the 1990s witnessed a number of challenges to its traditionally closed and expert committee-based regulatory style. The case of mad cow disease (bovine spongiform encephalopathy (BSE)) was to prove especially important in this regard. The 2000 Phillips Report into BSE concluded not only that a government department had provided inappropriate technical advice about the link between contaminated beef and human health, but also that relations with 'the public' had been badly managed. As the Report noted, at the core of government activity in this area had been a 'consuming fear of provoking an irrational public scare' (Phillips et al., 2000, p. 264). The same Report very directly pointed to a feeling of betrayal among members of the public: 'Confidence in public pronouncements about risk was a further casualty of BSE' (Phillips et al., 2000, p. xviii). In making such statements about a generalized loss of public confidence in scientific advice, the Phillips Report represented one important statement among a chorus of other calls at that time for greater openness in science–public–governmental relations. As an influential House of Lords Select Committee report put it also in 2000: "Policy makers will find it hard to win public support on any issue with a science component, unless the public's attitudes and values are recognized, respected and weighed along with the scientific and other factors" (House of Lords, 2000, p. 6). More widely, the Lords report emphasized a "new mood for dialogue" over science and technology and advocated a change in the culture of policy-making "so that it becomes normal to bring science and the public into dialogue about developments at an early stage" (House of Lords, 2000, p. 13).

From a social scientific perspective, there is much that could be said about this increased official enthusiasm for at least making statements about the need for greater transparency, dialogue, and engagement with the wider publics. A key point, however, is to note the relationship between a sense of crisis (or at least strain) in science–public relations and the call for dialogue and openness. This is very explicit in the official report into BSE, but also in a number of governmental and inter-governmental statements (for example, the European Commission's (2002) Action Plan on Science and Society). Presented in this fashion, PES is not simply a desirable option (perhaps on ethical or democratic grounds), but rather an essential precondition for the future of science-based innovation. In line with this assumption, governmental efforts toward engagement have been especially prominent in relation to developments that are either already controversial (including GM foods) or where public controversy is anticipated (nanotechnology, synthetic biology). In this situation, STS scholars have raised questions both about the real institutional commitment to change (Wynne, 2006) and the likelihood that greater openness will actually serve to 'rebuild' public trust: not least since public 'trust' in official experts in contemporary society will always be both conditional and relational, but also since there is little empirical evidence for a generalized (rather than selective) public mistrust in science (Felt and Wynne, 2007). Certainly, the notion that public trust can be 'fixed' by what are often time-limited and centrally directed initiatives in engagement is open to question on several grounds.

Frameworks of Consultation

As PES has developed into a field of institutional practice, STS scholars and others have paid particular attention to the form and the 'framing' of engagement initiatives (Irwin, 2001). Given the breadth of the issues in question and also their sociotechnical complexity, how could one even start to 'engage' with groups of citizens around sets of questions that are often both unfamiliar and externally selected? This question is further complicated by the potential diversity of 'the publics' (embracing, for example, both activists and those who consider themselves entirely new to the engagement topic) and the fundamental challenge of formulating an engagement focus that is appropriate to a diversity of parties and interests. In terms of engagement initiatives then, a number of practical but also social scientific questions arise concerning such matters as the form and organization of consultation, the balance of information-giving and dialogue, the framing of consultation agenda, and the degree of passivity or activity accorded to citizen groups. In addition, a tension can often be identified between the perceived need of institutional actors (e.g., civil servants) to move forward with policy processes (often within a relatively restricted time-frame) and the requirement to provide sufficient time and space for the treatment of what can turn out to be rather open-ended issues. This can be especially significant when issues that are originally presented in rather narrow terms (e.g., the commercial growing of GM crops in the UK) may take on broader significance within public discussions (Why should North American companies dictate to European consumers?; Has greater consumer choice had a positive or negative effect on national diets?; What is the relationship between GM foods and national self-sufficiency?).

Empirical accounts of specific engagement exercises have often reached rather negative conclusions concerning their restricted nature. These criticisms focus on the assumption in such exercises that 'engaged publics' are just 'out there' waiting for their views to be harvested, rather than being specifically shaped and constructed by the exercises themselves. On the one hand, and despite the expressed enthusiasm for public dialogue, such exercises have generally been atypical of institutional practice and limited to a small number of 'high-profile' topics. On the other, those exercises have been criticized for their restricted budget and timescales, the limitations of their coverage, a general lack of clarity about their aims and purposes, and the unproven link between specific engagement initiatives and actual policy change. Furthermore, many exercises in public engagement have taken form as relatively standardized investigations conducted by social research organizations, complete with demographically selected

participants and a mix of qualitative and quantitative evidence (i.e., smaller-scale focus groups together with larger-scale questionnaires). Coupled with a general sense that policy makers may be 'hitting the notes but missing the music' (Wynne, 2006), experience since 2000 suggests that the rhetoric of openness, dialogue, and engagement may be running at some distance from innovation and knowledge development processes (Felt and Wynne, 2007). While engagement therefore at least offers the possibility of 'opening up' policy and decision processes to new perspectives, knowledge, and opportunities, STS scholars and others have often concluded that the reality has been one of 'closing down,' as established modes of policy-making marginalize public concerns about the form and direction of technical change (Stirling, 2008). For this reason also, there has been some support for the idea of 'upstream engagement,' i.e., moves to enable public engagement earlier in the innovation process when policy choices and technological alternatives have not yet been 'closed down' (Wilsdon and Willis, 2004).

Science, Democracy, and Civic Epistemologies

One important contextual element to take into account when considering the relationship between science, technology, and democracy relates to the political and institutional cultures within which specific decisions are identified, defined, and enacted. Jasanoff has proposed the concept of 'civic epistemologies' to characterize the manner in which different societies employ different modes of reasoning when making decisions about science and technology. In her study of the development of biotechnology in the United States, Britain, and Germany, Jasanoff (2005) presents the management of the life sciences not as a 'special case' but as a field that is highly interwoven with larger processes of political constitution and nation-building. In contrast to universalistic discourses on science and democracy, this approach is highly attentive to the heterogeneity of (in this case) Western political cultures, and to the varying way in which these different political cultures interpret the credibility of public knowledge claims. Thus, taking one very notable example, the contemporary German treatment of stem cell research is inevitably influenced by the powerful national reaction to the eugenics policies of the Third Reich. The more general point is that particular cases and controversies around science and technology can only be fully interpreted in the context of longer-established, culturally situated practices of interpretation – and indeed that significant rifts have appeared in the ways in which leading Western nations address the governance of genetics and biotechnology. Going further, Jasanoff suggests that the politics of science and technology are central to the development of democratic theory, so that decisions over technically sophisticated areas such as biotechnology both reflect prevailing assumptions about democratic governance and also provoke a deeper reconsideration of what 'democracy' might mean within modern knowledge societies.

The argument that relations between science and democracy play out in specific political and cultural settings serves as an important reminder that 'public engagement' methods and discussions cannot necessarily or unproblematically be exported across local and national borders – and indeed that what counts as 'engagement' can appear very different in different environments. Thus, the international enthusiasm for 'Danish-style' consensus conferences typically disregards the cultural interconnections, social understandings, and national aspirations that led to the development of consensus conferences in Denmark – and which have both profoundly shaped their operation in that country and constituted a contextually specific definition of 'consensus' (Horst and Irwin, 2010). More broadly, comparative approaches to the relationship between science, politics, and democracy take us directly into the discussion with which this article began. While, at a general and philosophical level, there may indeed be 'little new' in the relationship between expert knowledge and the wider publics, current discussions over public engagement can also be viewed as symptomatic of a wider unease over the form and direction of technical change. To offer one obvious example, how are established forms of democratic governance to respond when so many key discussions over the direction of science and technology are taken within private corporations (Beck, 1992)? If, as STS scholars generally argue, science and politics cannot be kept apart from each other, then what are the consequences for political institutions which were not designed to deal with the potentially pervasive but also highly uncertain challenges offered by developments in fields such as medical and agricultural biotechnology (Callon et al., 2011)?

Science Communication as Engagement

While the STS literature has often defined PES in terms closely related to institutional policy, the politics of expertise and citizen action, an expanding cross-disciplinary literature has examined the public communication involved with science and technology in a fashion that both moves beyond 'deficit' formulations and explores significant science–public interactions occurring outside the structures of government and industry. Seen from a 'communication' perspective, popular science books, science journalism and the mass media, science museums, cinematic science, advertising and public relations, health campaigns, and the internet all represent significant domains in which the publics engage with science (Bucchi and Trench, 2008). Indeed, when compared with the scale and reach of such activities, even large-scale exercises such as the UK's 'GM Nation?' consultation appear extremely limited. It also follows that, for example, environmentalist groups and nongovernmental organizations are obliged to act as science communicators since "empirical claims about the state of the natural environment are core to their message" (Yearley, 2008, pp. 168–169). Equally, the design of novel experiments in communication (such as science installations) can offer a means of 'connecting' with citizens within the contexts of everyday life. Thus, Horst (2011) discusses one 'debate installation' on stem cell research located within a suburban shopping center. As with public consultation exercises, science communication can take many forms: from straightforward 'popular science' based on 'one-way, one-time' assumptions through to two-way and iterative models emphasizing dialogue and contextual understanding.

In line with more institutionally oriented treatments of PES, there have also been calls among researchers in science communication for 'knowledge coproduction' and science–public collaboration in shaping research agendas. Thus, Trench offers a triad of science communication models: 'deficit,' 'dialogue,' and 'participation.' In the third of these, "(c)ommunication about science takes place between diverse groups on the basis that all can contribute, and that all have a stake in the outcome of the deliberations and discussions" (Trench, 2008, p. 132).

One underlying question linking PES research conducted within a 'communication' framework with research focusing on planned consultation exercises concerns the extent to which 'science' is seen to be central to public perspectives and concerns. Thus, and as already noted with regard to the GM Nation? exercise, public views and assessments of possible areas of innovation may take into consideration a plurality of issues regarding choice, need, health, and ethics within which 'science' can at best appear marginal. Horst and Michael (2011) have noted the manner in which an installation with a specifically scientific focus was imaginatively reinterpreted and reconstructed by members of the public (as when teenage girls expressed their concern about the closure of the world's shopping centers or employed the installation's cameras for the amusement of their friends). We thus encounter an apparent paradox in which the 'science' in PES may be less central from certain social perspectives than many engagement protagonists would assume. Indeed, broader values and reflections about the form and direction of technical change – and about societal form and direction more generally – may override the specificities of particular issues (whether stem cell research, GM foods, or synthetic biology). In that way, the areas of science and technology that often serve as the stimulus to engagement activities (and which function as their very core) can turn out to be rather peripheral from a public viewpoint (which may explain some of the disappointment which often follows such activities). Seen from a broad social scientific perspective, this observation may appear unsurprising. However, it is an important point when seeking either to analyze or capture public assessments of particular scientific fields. It also alerts those studying PES to the possibility that there are alternative frameworks of meaning within everyday life, not all of which prioritize 'science' as a cultural and 'sense-making' category.

Engaging Beyond Engagement

In line with this discussion of forms of engagement that find places outside conventional political institutions and the established discourse of 'democracy and citizen action,' a number of STS scholars have sought to explore alternative ways in which members of society 'engage' with science and society, including the relationship between consumption and citizenship, and the manner in which public participation can be 'materialized' through objects and devices. Thus, Michael (1998) has sought to open up what he presents as a complex reciprocal relation between science and consumption, noting for example that the engagement between 'science' and 'the public' can be a matter of pleasure and an expression of identity (as in the enthusiastic purchasing of new electronic devices). The point is not to present the figure of 'the consumer' as an alternative to that of 'the citizen,' but rather to consider the implications of the rise of consumer culture and the aestheticization (or commercialization) of everyday life on the construction of the layperson. At the same time, Michael's account serves as a warning that PES studies should not present science–public relations in unidimensional terms: as if for example the sheep farmers in Wynne's study shared one coherent culture, one sense of identity, and one form of engagement with science and technology. The point instead is that individuals have multiple engagements with science and technology, not all of which can be captured in the established language of 'citizenship.'

Work by Marres and Lezaun (2011) has similarly attempted to pluralize the treatment of engagement by addressing the material dimensions of citizenship. Presented in this way, everyday activities – heating, cooking, washing – represent significant performances of engagement as, for example, choices are made concerning low-energy light bulbs, the level and location of thermostats, and the composting of household waste. More generally, material practices represent a significant domain of interaction with science and technology (Marres, 2012). Their study also places importance on people's actions, activities, and lived experiences around science and technology rather than viewing engagement primarily as a matter of knowledge and knowing. This is therefore an approach to engagement as if 'things' matter. It is also a challenge to develop an explicitly STS-centered reconsideration of the language of 'engagement' rather than simply borrowing from the established vocabulary of political theory.

The discussion of engagement as it occurs in a plurality of public and private contexts – and in both material and discursive forms – suggests above all that 'PES' as a field of scholarly investigation is far from complete. Certainly, there is considerable further potential for both exploring how publics are called into being within institutional approaches to engagement (see, for example, Felt and Fochler, 2010) and the diverse ways in which members of the public both engage and are engaged within sociotechnical systems. While the relationship between expert knowledge and the wider publics might not itself be new, the mutual entanglements, political implications, and sociotechnical manifestations embedded within that relationship remain a crucial focus for social science.

Abstract

Science has attracted the attention of sociologists both as a powerful source of institutional authority and as a set of practices for making and using knowledge. Theoretical and methodological orientations for the study of science have changed historically alongside shifts in the home discipline of sociology. Studies anchored in mid-C20 structural–functional thought gave way to newer approaches grounded in constructivism and ethnomethodology. These, in turn, were followed by work inspired by neoinstitutionalist and social structural frameworks. The key throughout is a sense that science is a social and cultural phenomenon, the upshot of historically and situationally contingent practices and not the expression of a universal epistemology or methodology.

The effort to make science the object of sociological analysis directs attention to the production and consumption of scientific knowledge in diverse cultural contexts, institutional structures, local organizations, and immediate settings. The sociology of science divides into three broad lines of inquiry, each distinguished by a particular mix of theories and methods. The earliest systematic studies (mostly from the 1950s to the early 1970s) focus on the structural contexts of scientists' behavior, addressing questions such as what rules govern the pursuit of scientific knowledge, how are scientists judged and rewarded, and how is scientific research broken up into dense networks of specialists? In the 1980s, sociologists shift their attention to the practices through which scientific knowledge is constructed – at the laboratory bench or in the rhetoric of professional papers. Starting in the 1990s, science is put in more encompassing societal contexts, as sociologists examine scientists along with other stakeholders as purveyors of cognitive authority, and explore their linkages to power, politics, and the economy.

Precursors

It is remarkable how much the literature in sociology of science is bunched into the last third of the twentieth century. Perhaps only after the deployment of nuclear weapons, or only after genetic engineering raised eugenic nightmares, could sociologists begin to think about science as a social problem in itself, rather than as a source of consistent solutions; or perhaps earlier generations of sociologists were guided by epistemological assumptions that rendered true scientific knowledge immune from social causes – thus putting it outside the orbit of sociological explanation.

Classical Anticipations

'Science' is nowhere indexed in Max Weber's encyclopedic *Economy and Society*, a measure of his unwillingness or inability to see it as a consequential factor in human behavior or social change. Weber's interest in science was largely methodological and political. Could the causal models employed so effectively in the natural sciences be used as well to study social action? Does the objectivity and neutrality of the social scientist preclude involvement in political activity?

Emile Durkheim also sought to institutionalize sociology by making its methods appear scientifically precise, but at the same time, he considered scientific knowledge as an object of sociological study. Durkheim suggested that basic categories of thought and logic (such as time and space) are social in origin, in that they correspond to fundamental social categories (such as the division of a society along lines of family or gender). However, as human societies grew in size and as their institutions became functionally differentiated, a distinctively scientific pursuit of knowledge was gradually insulated from such social causes. The observable facts of modern science, Durkheim concluded, were in accord with the reality of the physical world – a position that forestalled examination of how observable facts are also shaped by the culture and communities in which they arise.

Karl Marx's materialism would seem to commit him to the idea that all beliefs arise amid historically specific conditions of production, as they are shaped by the goals and interests of a ruling class. The rise of science in seventeenth-century Europe is intimately bound with the rise of industrial capitalism and, for Marx, can be explained in terms of the utilities of science-based technologies for improving productivity and enlarging surplus value. But, although the rate of scientific growth may be explained by its congruence with the interests of the bourgeoisie, Marx seems to suggest that the content of scientific claims inside professionalized research networks is nonideological – that is, science provides an objective account of natural reality.

Science in the Sociology of Knowledge

Even more surprising is the failure of systematic sociological studies of science to emerge from a blossoming sociology of knowledge in the 1920 and 1930s. Neither Max Scheler nor Karl Mannheim, authors of foundational treatises on the social determinants of knowledge, inspired sustained inquiry into the social determinants of science – probably because both distinguished scientific knowledge from other kinds in a way

that truncated what sociology could say about it. Scheler isolated the content of scientific knowledge – and the criteria for ascertaining validity – by describing such criteria as absolute and timeless, and not shaped by social interests. The effects of social structure (specifically, the power of ruling elites) is limited to selections of problems and beliefs from that self-contained and essential realm of ideas.

Mannheim sustained the neo-Kantian distinction between formal knowledge of the exact sciences and sociohistorical knowledge of culture. Phenomena of the natural world are invariant, Mannheim suggests, and so therefore are criteria for deciding truth (i.e., impartial observations based on accurate measurements). In contrast, cultural phenomena become meaningful only as they are constructed through interest-laden judgments of significance, which are neither impartial nor invariant, and thus they are amenable to sociological explanation.

Robert K. Merton's 1938 classic *Science, Technology and Society in Seventeenth-century England* (see Merton, 1973) tackles a fundamental problem: why did modern science emerge with a flourish in seventeenth-century England? His answer has become known as the 'Merton Thesis': that a Puritan ethos provided both the motivating force and legitimating authority for the pursuit of scientific inquiry. Certain religious beliefs – e.g., God is glorified by an appreciation of his handiwork in Nature, or Blessed Reason separates human from beast – created a fertile cultural context for the rise of science. Merton also explains shifts in the foci of research attention among the early modern 'natural philosophers' by connecting empirical inquiry to the search for technological solutions to practical problems in mining, navigation, and ballistics.

Social Organization of the Scientific Community

When concerted sociological studies of science began in the late 1950 and 1960s, research centered on the institutions or social structures of science – with relatively less attention given to the routine practices involved in making knowledge or to the wider settings in which science was conducted. This work was largely inspired by theories of structural–functional analysis, which ask how the community of scientists is organized in order to satisfy modern society's need for certified, reliable knowledge. One distinctive feature of this first phase is a reliance on quantitative methods of analysis. With statistical data drawn from surveys of scientists and from the *Science Citation Index* (and other bibliometric sources), sociologists developed causal models to explain individual variations in research productivity and used topographical techniques such as multidimensional scaling to map the dense networks of scientists working at a research front (Barber and Hirsch, 1962; Hagstrom, 1965; Crane, 1972).

Norms of Science

The shift from analyzing science in society to analyzing its internal social organization was effected in Merton's 1942 paper on the normative structure of science (reprinted as a revised and retitled chapter in Merton, 1973). Writing in the shadow of Nazism, Merton argues that the success of scientists in extending certified knowledge depends, at once, on a salutary political context (namely, democracy, which allows science a measure of autonomy from political intrusions and whose values are said to be congruent with those of science – quite unlike fascism) and on an internal institutionalized ethos of values held to be binding upon the behavior of scientists. This ethos comprised the famous norms of science: scientists should evaluate claims impersonally (universalism), share all findings (communism), never sacrifice truth for personal gain (disinterestedness), and always question authority (organized skepticism). Behavior consonant with these moral expectations is functional for the growth of reliable knowledge, and for that reason, young scientists learn through precept how they are expected to behave, conformity is rewarded, and transgressions are met with outrage.

Subsequent work ignored Merton's conjectures about science and democracy, as sociologists instead pursued implications of the four social norms. Studies of behavioral departures from these norms – ethnocentrism, secrecy, fraud, plagiarism, dogmatism – precipitated debates over whether such deviance is best explained by idiosyncratic characteristics of a few bad apples or changing structural circumstances (such as commercialization of research) that might trigger increases in such behavior. Sociologists continue to debate the possibility that Merton's norms are better explained as useful ideological justifications of scientists' autonomy and cognitive authority. Other research suggests that the norms guiding scientific conduct vary historically, vary among disciplines, vary among organizational contexts (university research vs military or corporate research), and vary even in their situational interpretation, negotiation, and deployment – raising questions about whether the norms identified by Merton are functionally necessary for enlarging scientific knowledge.

Stratification and Scientific Careers

The norm of universalism in particular has elicited much empirical research, perhaps because it raises questions of generic sociological interest: how is scientific performance judged, and how are inequalities in the allocation of rewards and resources best described and explained? With effective quantitative measures of individual productivity (number of publications or citations to one's work), resources (grant dollars), and rewards (prizes, like the Nobel), sociologists have examined with considerable precision the determinants of individual career success or failure. Competition among scientists is intense, and the extent of inequality high: the distribution of resources and rewards in science is highly skewed. A small proportion of scientists publish most research papers (and those papers collect most citations), compete successfully for research grants and prestigious teaching posts, achieve international visibility and recognition, and win cherished prizes.

Debate centers on whether these observed inequalities in the reward system of science are compatible with the norm of universalism – which demands that contributions to knowledge be judged on their scientific merit, with resources and opportunities meted out in accordance with those judgments. The apparent elitism of science may result from an 'accumulation of advantage': work by relatively more eminent or

well-positioned scientists is simply noticed more and thus tends to receive disproportional credit – which (over time) enlarges the gap between the few very successful scientists and everybody else. Such a process may still be universalistic because it is functional for the institutional goal of improving science: giving greater attention to research of those with accomplished track records may be an efficient triage of the overwhelming number of new candidate theories or findings. Others suggest that particularism contributes to the stratification of scientists – old boy networks that protect turf and career reputations by rewarding sycophants. The underrepresentation of women in the higher echelons of science has called attention to sometimes subtle sexism that occurs early in the scientific career (restricted access to well-connected mentors or essential research equipment, or opportunities to collaborate and assignment to trivial problems or mind-numbing tasks) (Long and Fox, 1995; also see Lincoln et al., 2012 for recent work on the 'Matilda Effect').

Institutionalization of the Scientific Role

A separate line of sociological inquiry (exemplified in work by Joseph Ben-David (1991) and Edward Shils) seeks an explanation for how science first became a remunerable occupation – and later, a profession. How did the role of the scientist emerge from historically antecedent career patterns in which amateurs explored nature part-time and generally at their own expense? The arrival of the 'scientist' as an occupational self-identification with distinctive obligations and prerogatives is inseparable from the institutionalization of the modern university (itself dependent upon government patronage). Universities provided the organizational form in which the practice of science could become a full-time career – by fusing research with teaching, by allowing (ironically) the historic prestige of universities as centers of theology and scholasticism to valorize the new science, and by providing a bureaucratic means of paying wages and advancing careers.

The scientific role has also been institutionalized in corporate and government laboratories. The difficulties of transporting a 'pure science' ideal of university-based research into these very different organizational settings have been the object of considerable sociological attention. Scientists in industry or government face a variety of competing demands: their research is often directed to projects linked to potential profits or policy issues rather than steered by the agenda of their discipline or specialty; the need to maintain trade secrets or national security hampers the ability of scientists in these settings to publicize their work and receive recognition for it. And, as Jerome Ravetz (1971) suggests, the intrusion of 'bureaucratic rationality' into corporate and state science compromises the craft character of scientific work: largely implicit understandings and skills shared by the community of scientists and vital for the sustained accumulation of scientific wisdom have little place in accountabilities driven by the bottom line or policy relevance.

Disciplines and Specialties

Sociologists use a variety of empirical indicators to measure the social and cognitive connections among scientists: self-reports of those with whom a scientist exchanges ideas or preprints, subject classifications of publications in topical indexes or abstract journals, lineages of mentor–student relationships or collaborations, and patterns of who cites whom or is cited with whom ('cocitation'). The networks formed by such linkages show occasional dense clusters of small numbers of scientists whose informal communications are frequent, who typically cite each other's very recent papers, and whose research focuses on some new theory, innovative method, or breakthrough problem. Emergence of these clusters – for example, the birth of radio astronomy in England after Second World War (WWII), as described by David Edge and Michael Mulkay (1976) – is a signal that science has changed, both cognitively and socially: new beliefs and practices are ensconced in new centers for training or research with different leaders and rafts of graduate students. Over time, these specialties evolve in a patterned way: the number of scientists in the network becomes much larger and connections among them more diffuse; the field gets institutionalized with the creation of its own journals and professional associations; and precedent-shattering innovations become less common as scientists work more on filling in details or adding precision to the now-aging research framework. As one specialty matures, another dense cluster of scientists emerges elsewhere, as the research front or cutting edge moves on. More recent sociological research, following the theoretical lead of Pierre Bourdieu (2004), sees specialties and disciplines as occasions for competitive struggle among scientists seeking to advance careers by advancing their preferred understanding of reality.

Sociology of Scientific Knowledge

A sea-change in sociological studies of science began in the 1970s with a growing awareness that studies of the institutional and organizational contexts shaping scientists' behavior could not illuminate sufficiently the processes that make science: experimental tinkering, sifting of evidence, negotiation of claims, replacement of old beliefs about nature with new ones, and achievement of consensus over the truth. All these processes – observation, getting instruments and research materials (e.g., mice) to work, logic, criteria for justifying a finding as worthy of assent, choices among theories, putting arguments into words or pictures, persuading other scientists that one is correct – are uncompromisingly social, cultural, and historical phenomena, and so sociologists set about to explain and interpret the content of scientific knowledge by studying the routine practices of scientific work.

This research is guided by constructivist theories (and, less often, ethnomethodology), which center attention on the practically accomplished character of social life. Rather than allow a priori nature or given social structures to explain behavior or belief, constructivist sociologists examine how actors incessantly make and remake the structural conditions in which they work. Such research relies methodologically on historical case studies of scientific debate, up close ethnographic observations of scientific practices, and interpretative analysis of scientific texts (Mulkay, 1979, 1980; Knorr-Cetina and Mulkay, 1983).

Sociology of Discovery

Diverse studies of scientific discovery illustrate the range of sociological perspectives brought to bear on these consequential events. An early line of inquiry focuses on the social and cognitive contexts that cause the timing and placing of discoveries: why did these scientists achieve a breakthrough then and there? Historical evidence points to a pattern of simultaneous, multiple, and independent discoveries – that is, it is rare for a discovery to be made by a scientist (or a local team) who is the only one in the world doing research on that specific question. Because honor and recognition are greatest for solutions to the perceivably 'hottest' problems in a discipline, the best scientists are encouraged by the reward system of science to tackle similar lines of research. But these same social structures can also forestall discovery or engender resistance to novel claims (Brannigan, 1981). Cognitive commitments to a long-established way of seeing the natural world (reinforced by reputations and resources that depend upon those traditional perspectives) can make it difficult for scientists to see the worthiness of a new paradigm. Resistance to new ideas seems to be greatest among older scientists, especially in cases where the proposed discovery comes from scientists with little visibility or stature within the specialty or discipline that would be transformed.

More recent sociological research considers the very idea of 'discovery' to be a practical accomplishment of scientists. Studies inspired by ethnomethodology offer detailed descriptions of scientific work 'first time through,' taking note of how scientists at the laboratory bench decide whether a particular observation (among the myriad observations) constitutes a discovery (Garfinkel et al., 1981). Other sociologists locate the 'moment' of discovery in downstream interpretative work, as scientists narrate first time through research work with labels such as 'breakthrough.' Such discovery accounts are often sites of dissensus, as scientists dispute the timing or implications of an alleged discovery amid ongoing judgments of its significance for subsequent research initiatives or allocations of resources. These themes – interests, changing beliefs, ordinary scientific work, post hoc accountings, dissent, and persuasion – have become hallmarks of the sociology of scientific knowledge.

Interests and Knowledge Change

In the mid-1970s to the 1980s, sociology of science took root at the Science Studies Unit in Edinburgh, as philosopher David Bloor developed the 'strong programme,' while Barry Barnes, Steven Shapin, Donald MacKenzie, and Andrew Pickering developed its sociological analog – the 'interest model.' The goal is to provide causal explanations for changes in knowledge – say, the shift from one scientific understanding of nature to a different one. Scientists themselves, as well as philosophers of science, might account for such changes in terms of greater evidence, coherence, robustness, promise, parsimony, predictive power, or utility of the new framework. Sociologists, in turn, account for those judgments in terms of social interests of scientists that are either extended or compromised by a decision to shift to the new perspective. What becomes knowledge is thus contingent upon the criteria used by a particular community of inquirers to judge competing understandings of nature, and also upon the goals and interests that shape their interpretation and deployment of those criteria. Several caveats are noted: interests are not connected to social positions (class, for example, or nationality, discipline, specialty) in a rigidly deterministic way; social interests may change along with changes in knowledge; and choices among candidate knowledge claims are not merely strategic – that is, calculations of material or symbolic gains are bounded by considerable uncertainty and by a shared culture of inquiry that provides standards for logical or evidential adequacy and for the proper use of an apparatus or concept.

Drawing on historical case studies of theoretical disputes in science – nineteenth-century debates over phrenology and statistical theory and twentieth-century debates among high-energy physicists over quarks – two different kinds of interests are causally connected to knowledge change. Political or ideological commitments can shape scientists' judgments about candidate knowledge claims: the development of statistical theories of correlation and regression by Francis Galton, Karl Pearson, and R. A. Fisher depended vitally on the utility of such measures for eugenic objectives. Different social interests arise from the accumulated expertise in working with certain instruments or procedures, which incline scientists to prefer theories or models that allow them to capitalize on those skills (Barnes and Edge, 1982; Barnes et al., 1996).

Laboratory Practices and Scientific Discourse

As sociologists moved ever closer to the actual processes of 'doing science,' their research divided into two lines of inquiry: some went directly to the laboratory bench seeking ethnographic observations of scientists' practices in situ and others examined scientists' discourse in talk and texts – that is, their accounting practices. These studies together point to an inescapable conclusion: there is nothing not social about science. From the step-by-step procedures of an experiment to writing up discovered facts for journal publication, what scientists do is describable and explicable only as social action – meaningful choices contingent on technical, cognitive, cultural, and material circumstances that are immediate, transient, and largely of the scientists' own making.

Laboratory ethnographies by Karin Knorr-Cetina (1999), Michael Lynch (1993), and Bruno Latour and Steve Woolgar (1986) reveal a science whose order is not to be found in transcendent timeless rules of 'scientific method' or 'good laboratory procedures,' but in the circumstantial, pragmatic, revisable, and iterative choices and projects that constitute scientific work. These naturalistic studies emphasize the local character of scientific practice: the idea that knowledge making is a process situated in particular places with only these pieces of equipment or research materials or colleagues immediately available. Never sure about how things will turn out in the end, scientists incessantly revise the tasks at hand as they try to get machines to perform properly, control wild nature, interpret results, placate doubting collaborators, and rationalize failures. Even methodical procedures widely assumed to be responsible for the objective, definitive, and impersonal character of scientific claims – experimental replication, for instance – are

found to be shot through with negotiated, often implicit, and potentially endless judgments about the competence of other experimentalists and the fidelity of their replication attempts to the original (as Harry Collins (1992) has suggested).

Ethnographic studies of how scientists construct knowledge in laboratories compelled sociologists then to figure out how the outcomes of those mundane contextual practices (hard facts, established theories) could paradoxically appear so unconstructed – as if they were given in nature all along, and now just found (not made). Attention turned to the succession of 'inscriptions' through which observations become knowledge – from machine-output to laboratory notebook to draft manuscript to published report. Scientists' sequenced accounts of their fact making rhetorically erase the messy indeterminacy and opportunism that sociologists have observed at the laboratory bench, and substitute a story of logic, method, and inevitability in which nature is externalized as waiting to be discovered. Such studies of scientific discourse have opened up an enduring debate among constructivist sociologists of science: those seeking causal explanations for scientists' beliefs treat interests as definitively describable by the analyst, while others (Gilbert and Mulkay, 1984; Woolgar, 1988) suggest that sociologists must respect the diversity of participants' discursive accounts of their interests, actions, or beliefs – and thus treat actors' talk and text not as mediating the phenomena of study but as constituting them.

Actor Networks and Social Worlds

After sociologists worked to show how science is a thoroughly social thing, Bruno Latour (1987) and Michel Callon (1986) retrieved and reinserted the material: consequently, science is not only about facts, theories, interests, rhetoric, and power but also about nature and machines. Scientists accomplish facts and theories by building 'heterogeneous networks' consisting of experimental devices, research materials, images and descriptive statistics, abstract concepts and theories, the findings of other scientists, as well as persuasive texts – and, importantly, none of these are reducible to any one of them, nor to social interests. Things, machines, humans, and interests are, in the practices of scientists, unendingly interdefined in and through these networks. They take on meanings via their linkages to other 'actants' (a semiotic term for anything that has 'force' or consequence, regardless of substance or form). In reporting their results, scientists buttress claims by connecting them to as many different actants as they can, in hopes of defending the putative fact or theory against the assault of real or potential dissenters. From this perspective, length makes strength, that is, the more allies enrolled and aligned into a network – especially if that network is then stabilized or 'black boxed' – the less likely it is that dissenters will succeed in disentangling the actants and thereby weaken or kill the claim. Importantly, for this sociology of science, the human and the social are decentered, in an ontology that also ascribes agency to objects of nature or experimental apparatuses.

Actor-network theory moved the sociological study of science back outside the laboratory and professional journal – or, rather, reframed the very idea of inside and outside. Scientists and their allies 'change the world' in the course of making secure their claims about nature, and in the same manner. In Latourian vernacular, not only are other scientists, bits of nature, or empirical data enlisted and regimented but also political bodies, protest movements, the media, laws, and hoi polloi. When Louis Pasteur transformed French society by linking together microbes, anthrax, microscopes, laboratories, sick livestock, angry farmers, nervous Parisian milk drinkers, public health officials, lawmakers, and journalists into what becomes a 'momentous discovery,' the boundary between science and the rest of society became impossible to locate. Scientists are able to work autonomously at their benches precisely because so many others outside the laboratory are also 'doing science,' providing the life support (money, epistemic acquiescence, infrastructure) on which science depends.

The boundaries of science also emerge as theoretically interesting in related studies derived from the brand of symbolic interactionism developed by Everett Hughes, Herbert Blumer, Anselm Strauss, and Howard Becker (and extended into research on science by Adele Clarke (1990), Joan Fujimura, and Susan Leigh Star). On this score, science is work – and, instructively, not unlike work of any other kind. Scientists (like plumbers) pursue doable problems, where 'doability' involves the articulation of tasks across various levels of work organization: the experiment (disciplining research subjects), the laboratory (dividing labor among laboratory technicians, graduate students, and postdocs), and 'social worlds' (the wider discipline, funding agencies, or maybe animal rights activists) (Fujimura, 1987). Scientific problems become increasingly doable when 'boundary objects' allow for cooperative intersections of those working on discrete projects in different social worlds. For example, success in building California's Museum of Vertebrate Zoology in the early twentieth century depended upon the standardization of collection and preparation practices (here, the specimens themselves become boundary objects) that enabled biologists to align their work with trappers, farmers, and amateur naturalists in different social worlds (Star and Griesemer, 1989). As in actor-network theory, sociologists working in the 'social worlds' tradition make no assumption about where science leaves off and the rest of society begins – those boundaries get settled only provisionally, and remain open to challenge from those inside and out.

Science In/As Society

Recent work seeks an even better understanding of how science intersects with economic interests, political action, and cultural traditions. Sheila Jasanoff's (2005) development of the idiom of the 'coproduction' of science and society suggests that the construction of scientific knowledge is at the same time the resolution (or perpetuation) of political, economic, and cultural controversies. That is, science changes along with other social institutions and practices, simultaneously and interactively. Attention has centered on an increasingly expanding set of stakeholders, who engage 'science' either as producers or consumers, beneficiaries, or victims. These newer studies build on a foundation created by the sociology of scientific

knowledge, even as they increasingly draw on the institutionalist inclinations of an earlier generation.

Credibility and Expertise

Science is often examined as a cognitive or epistemic authority; scientists are said to have the legitimate power to define facts and assess claims to truth. This authority is not treated as an inevitable result of the character or virtue of those who become scientists, the institutional organization of science (norms, for example), or the 'scientific method.' It is, rather, an accomplished resource pursued strategically by a profession committed not only to extending knowledge but also to preserving and expanding its power, patronage, prestige, and autonomy.

Steven Shapin (1994), among others, has identified credibility as a constitutive problem for the sociology of science. Whose knowledge claims are accepted as believable, trustworthy, true, or reliably useful – and on what grounds? Plainly, contingent judgments of the validity of claims depend upon judgments of the credibility of the claimants. Examination of such judgments in historical and contemporary cases has focused sociological attention on how people use (as they define) qualities such as objectivity, expertise, competence, personal familiarity, propriety, and sincerity to decide which candidate in the universe becomes provisionally 'real.' A long-established line of sociological research examines those public controversies that hinge, in part, on 'technical' issues. Case studies of disputes over environmental and health risks find a profound ambivalence: the desire for public policy to be decided by appropriate legislative or judicial bodies in a way that is both understandable and accountable to the populace runs up against the need for expert skills and knowledge monopolized by scientific, medical, or engineering professionals.

The understanding of science today has benefited from those who bring to its analysis theories and methods from the sociological study of social movements and participatory politics. Steven Epstein (1998) develops the concept of 'credibility struggles' through a study of the science and politics of acquired immunodeficiency syndrome (AIDS). Initially, activists denounced scientific research on AIDS as unresponsive to the immediate needs of those who suffered. Then the activists shifted tactics, and sought a 'seat at the table' by learning enough about clinical trials and drug development to work alongside scientists in the deliberation of public policy. In other cases, scientists themselves become activists and embrace the agendas of various social movements (such as physicists and others who worked to resist the proliferation of nuclear weapons after WWII or the spread of artificial pesticides and herbicides). This line of inquiry has crystallized in a 'new political sociology of science,' which is especially sensitive to the diversity of stakeholders who variously challenge and exploit the cognitive authority of science in the pursuit of political, economic, or personal ambitions (Frickel and Moore, 2006; also see Kloppenburg, 1988).

Situating Science

Finally, sociologists have turned their attention to a different question: *Where* does science happen (Gieryn, 1999). Some explore the collaborative networks and organizational settings that house scientific inquiry – beyond the archetypal pure science laboratory at a university. Careers of scientists at work in the entrepreneurial networks of Silicon Valley vary substantially from those of academic researchers, as patents become as important for success as open publications (Bunker Whittington et al., 2009). Other scholars compare the distinctive trajectories of scientific research and application as these emerge in different national settings. For example, because of distinctive political, economic, and legal contexts that are themselves never fixed, biotechnological knowledge and products move along different developmental and regulatory trajectories in the United States, United Kingdom, and Germany (Jasanoff, 2005). Sociologists working from a neoinstitutionalist perspective examine the role of science in the global universalization of standards and categories, as the legitimating force of scientific authority is adopted locally (but eventually almost everywhere) to justify and rationalize political actions and structures (Drori et al., 2002). Other scholars have countered with an assertion that science itself is an inescapably local production, shaped thoroughly by the cultural, spatial, material, and even architectural particularities of sites where research is conducted. Studies of laboratory design and of the unique qualities of local field sites have initiated a promising geographic sociology of science.

This article is a revision of the previous edition article by Z. Chen, R. Siegler, volume 20, pp. 13714–13719, © 2001, Elsevier Ltd.

Abstract

Children's understanding of scientific concepts begins in infancy, but develops considerably with experience over many years. Focusing primarily on from the past 20 years, we discuss the development of scientific concepts in three sections: understanding of physical concepts, understanding of biological concepts, and scientific learning processes – both how children learn science and how they learn the processes involved in scientific reasoning.

Early Understanding of Scientific Concepts

As Chen and Siegler discussed in 2001, the advancement of technology such as eye trackers over more action-oriented measures has provided support for much earlier acquisition of science knowledge. Using looking time paradigms, such as the violation of expectancy (see Chen and Siegler's previous version), researchers have found that infants have at least immature theories of scientific concepts, such as physics (Vosniadou, 2002) and biology (Setoh et al., 2013). These paradigms record infant visual fixations to stimuli presented on a computer or television screen and provide a more sensitive measure than previous methods by eliminating task demands. Recent evidence from looking time experiments provides support that children as young as 4-month old demonstrate basic physical knowledge, such as showing surprise when a solid object appears to move through another solid object, when an event violates the rules of gravity, or when an inanimate object moves without a force being applied (Wang et al., 2005; Baillarageon et al., 2009), and by the age of 3, children have a strong understanding of the differences between animate and inanimate objects (see below for evidence of this in younger infants as well; see Chen and Siegler's previous version). Though these studies suggest some early understanding of science concepts, children's science knowledge is quite immature relative to adults,' and develops significantly from early childhood through adulthood. Similarly, children have basic scientific process skills, though some researchers consider their learning processes to be quite sophisticated, calling infants 'rational constructivists' who can reason about evidence with previous knowledge and beliefs using probabilities (Xu and Kushnir, 2013). We discuss the development of scientific concepts in three sections: understanding of physical concepts, understanding of biological concepts, and scientific learning processes.

Developing Understanding of Physical Concepts

Though understanding physical concepts requires quite abstract thought, there is consistent support that children begin to demonstrate the basic understanding of physical phenomena from a very young age. It is suggested that this knowledge of the physical world evolved as a mechanism of survival (Pinker, 1997; Wellman and Gelman, 1998), for example, understanding the principle of consistency in solid objects. Children demonstrate understanding of the rule that objects continue to exist when not visible (i.e., object permanence), or that partially occluded objects are continuous (Piaget, 1952; Baillargéon et al., 1995; Baillargéon, 2008). Infants well under 1 year seem to make sense of the physical world, for example, demonstrating understanding that large items can be hidden by large containers but not small containers (Hespos and Baillargéon, 2006), and recognizing violations of laws of physics like gravity (Luo et al., 2009). While some researchers suggest that this early appearance of physical knowledge is innate, there is evidence supporting the relationship between children's experience and their understanding of physical relationships in the world (Cicchino et al., 2011).

A key area where infants and very young children tend to show weaker understanding of physical concepts is in mechanistic thinking. Children's understanding of the world is greatly enhanced with the ability to make causal inferences (Frye et al., 1996), and determining mechanisms is critical for developing accurate theories of causal relationships. However, infants and young children tend to represent causal relationships using relatively weak rules, such as covariation (Gopnik et al., 2001). When events occur together, they perceive them as causally connected. If one event tends to precede another in time or space, it is inferred to be the causal agent. Children eventually begin to invent mechanisms to explain these relationships – often incorrect – creating naive or folk theories. It is not until they learn the correct mechanisms that their theories are considered to be more scientific than naive, and the theories become more useful in understanding the physical world (Keil, 2010).

The development of children's ability to understand mechanisms is not clear. While some research suggests that children must be explicitly taught, it has also been suggested that preschool children can infer even abstract causal mechanisms with limited evidence (Schulz et al., 2008). For example, after seeing only four demonstrations of three causal kinds of blocks, children are able to infer the mechanistic power of a novel block with only a single demonstration. The three causal relationships were: block B makes a train noise when it comes in contact with block A, block C makes a siren noise when it comes in contact with block B, but contact between blocks A and C has no effect. When children are shown one instance of a novel block's effect on block B – seeing it causes

block B to make a train noise – they are then able to infer that if the novel block is placed behind a curtain and makes a train sound, that there must be another block, specifically a B block, also behind the curtain. Though young children demonstrate causal reasoning across several similar studies, this ability seems to be limited by their tendency to focus on a single causal mechanism (e.g., when two blocks touch, a sound plays; when a switch is flipped, a light comes on). An example of this limitation is observed in children's understanding of force dynamics.

Though children can reason about causality and make predictions of motion events in their first year of life, the weakness of their understanding is demonstrated in their failure on tasks involving multiple forces. For example, when preschool age children predict what will happen when a ball rolls off of a table, they expect the ball to fall straight down, rather than following a parabolic path. Göksun et al. (2013) investigated children's representations of multiple forces by asking children to make predictions in events with two forces: motion caused from a ball rolling out from a 16″ tall curved tube, and wind caused from a blower. The researchers asked children to estimate where the ball would roll in three conditions, determined by the types of causal forces: (1) a single force acting on the ball (cause), (2) two forces acting on the ball in the same direction (enable), and (3) two forces acting on the ball in opposing directions, either directly opposing each other or at a perpendicular angle (prevent). The researchers found that children were relatively accurate when predicting where the ball would roll if acted on by a single force (cause), but were not able to integrate two forces in their predictions until about 5.5 years of age. When integrating two forces, children were most accurate when the forces were moving in the same direction (enable) and much less accurate when forces were perpendicular than directly opposing each other (prevent).

Children's developing concepts of physical events involves an underlying and understudied aspect of the development of physical concepts: spatial reasoning. The development of children's ability to reason about space is fundamental in their ability to make predictions about causal relationships and about the laws of physics. Yet, little is known about when and how different spatial abilities develop. One major developmental milestone that children must reach in order to understand the physical world more accurately is to overcome egocentrism, or the ability to consider perspectives other than one's own, which typically occurs during the preschool years (see Newcombe, 1989). Object representation, discussed above, is also a part of spatial ability, though it goes beyond only representing objects to being able to rotate and transform them, for example, determining which way to orient puzzle pieces so they fit together, or inferring the shape of a cross section of an object. Mental rotation, the imagined movement of an object in space, is an ability seen as early as infancy (Möhring and Frick, 2013), but with a strong developmental trend through early childhood (Frick et al., 2013), and malleability, or sensitivity to intervention, even into adulthood. Spatial tools, for example, symbolic representation, gesture, and sketching, can also be used to learn about one's representation of the physical world, and understanding of spatial representations is foundational for important scientific skills (DeLoache, 1987). Children's ability to use very simple maps from 3 to 4 years of age suggests relatively accurate but simple mental representations of physical space, and research on the use of symbolic representations demonstrates considerable development from early childhood through adulthood, including the strategies used in the use of representations, for example, a switch from very perceptual to more metric or quantitative methods.

Though infants and young children do not typically hold complex representations of physical concepts and space, research suggests that they are quite capable of encoding information to form sufficient representations of physical events, allowing them to use their representations to recognize, categorize, and predict in the physical domain (Baillargéon et al., 2009). These representations and the ability to use them, however, are very limited, resulting in a 'naive' or 'folk' theory of physical concepts that develops considerably throughout adolescence and beyond.

Developing Understanding of Biological Concepts

Although there is still considerable debate regarding early understanding of biological concepts including life, aging, reproduction, illness, and death, researchers generally agree that young children demonstrate more sophisticated knowledge than originally proposed by Piaget (1929). A review of the contributions since the late 1990s highlights two critical factors. First, young children may have a more nuanced appreciation of biological concepts than previously thought, but important conceptual development can be observed in childhood, adolescence, and even adulthood. Second, much of what children understand about biological concepts is learned from others (Gelman, 2009) and thus, must consider the role of linguistic and sociocultural environment in their formation.

Recent evidence has identified early sensitivity to unique biological characteristics such as gaze alternation, face recognition, and biological motion within 1 year (Bidet-Ildei et al., 2013; Brand et al., 2007; de Haan et al., 2002). For example, infants can distinguish between animate and inanimate objects (Rakison and Poulin-Dubois, 2001; Woodward et al., 2001) and recognize that self-propelled movement is unique to animals (Kosugi et al., 2003). In addition, young infants anticipate that human hands, but not trains or blocks are associated with *causal agency*, or an entity's ability to contact other objects and change their physical location (Saxe et al., 2005). While these early sensitivities may provide a foundation for developing biological understanding, these representations are not necessarily aligned with the concepts of children and adults. In particular, early understanding of living things (e.g., animate entities) may conflate the perception of humanlike features and prototypical knowledge about intentional agents. At 6.5 months, for example, infants considered actions to be goal-directed when performed by a human or a humanoid robot (Kamewari et al., 2005). By 18 months, in contrast, children may be more likely to accurately categorize entities into inclusionary animate and inanimate categories even if the exemplars are perceptually distinct (e.g., people/horses; furniture/vehicles; Rostad et al., 2012).

Despite evidence for conceptual foundations in infancy, early understanding of biological concepts often involves substantial misconceptions that undergo significant change with age and experience (Inagaki and Hatano, 2002). In one study that evaluated parental reports of biological misconceptions in 3- to 6-year-old children, a majority involved the misunderstanding of causal processes or events involved in biological phenomena such as reproduction or illness, and the outcome or inevitability of aging and death (Nguyen and Rosengren, 2004).

One important developmental shift involves children's ability to overcome perceptual biases and appreciate that biological concepts share an essence that transcends surface characteristics. In one study that demonstrates this shift, Keleman et al. (2003) presented 3-, 4-, and 5-year-old children with information about the contrasting behavioral properties of two 'training' animals (e.g., a surgeonfish and a porcupine). Similar to the triad induction task developed by Gelman and Markman (1986), they were then asked which of these properties was true of a test animal (e.g., a porcupine box fish) that had overall similarity to one of the training animals (i.e., the surgeonfish) but was overall dissimilar to the other training animal (i.e., porcupine) with which it shared only a behaviorally relevant functional structure (i.e., spines). Results suggest that 4 and 5 year olds (but not 3 year olds) were more likely to overlook global perceptual similarity and attend to relevant functional cues (despite perceptual dissimilarity) as a basis for generalizing the biologically based property (i.e., its defensive strategy). Furthermore, by 4 years of age, children were increasingly able to reflect on and describe their attention to functional features when explaining why they believe animals do what they do.

Additional changes in children's ability to make inferences about functional properties can be observed from 5 to 10 years of age (Farrar and Boyer-Pennington, 2011). In this study, children learned familiar or unfamiliar internal, external, or functional properties of known and unknown animals. Younger children's beliefs about the essence of biological kinds were more likely to be guided by perceptual appearance rather than categorical information, and gave no selective importance to internal properties. Older children, however, made categorical inferences about internal and functional properties even if they were unfamiliar. As children become more knowledgeable about biology, they are able to more accurately weigh categorical vs perceptual information in the context of the specific task to distinguish which property types are likely to be shared. Although misconceptions become less prevalent with age and experience, traces may persist into adolescence and even adulthood. In a speeded classification task, adult undergraduates showed reduced accuracy and increased response times when determining life status for plants, relative to animals, and for natural and moving nonliving things compared with artifacts and nonmoving things (Goldberg and Tompson-Schill, 2009). Surprisingly, these results were replicated in a group of university biology professors, suggesting that feature biases within biological knowledge appear to reflect developmental foundations that are not completely erased with the acquisition of domain-specific expertise.

Given that certain biological processes are difficult to directly observe, these concepts may develop to a large extent through cultural transmission. Converging evidence suggests that culture and experience matter when reasoning about biological phenomena (Medin et al., 2010). Tarlowski (2006) tested four groups of 4 year olds differing along two dimensions of exposure to biological information: their direct experience with nature (i.e., urban or rural) and the biological expertise of their parents (i.e., experts vs laypeople). Results showed that children's exposure to biology had consequences for their patterns of induction: children of experts based inductions on the category *animal*, while children of laypeople relied on similarity. Furthermore, rural children were more restricted in their responses compared to urban children. In another study, 5- to 7-year-old Menominee and European American children were shown pairs of plants and animals and given the opportunity to describe how or why they might be associated (Unsworth et al., 2012). Menominee children were more likely than their rural European American counterparts to talk about their ecological relations and utility associated with nature. They were also more likely to mimic the species using sound or posture, suggesting a greater psychological closeness to nature. These findings suggest that biological concept formation is not just a product of development, but is highly contingent upon children's experience.

The persistent challenges observed when drawing distinction between living and nonliving natural kinds is complicated by the fact that different languages carve up and categorize these concepts in distinct ways. For example, the term 'alive' introduces challenges to English-speaking children since it can be applied to an inclusive category of all animate objects as well as the more restrictive concept that excludes humans. This is less problematic in other languages such as Indonesian in which the term 'alive' refers only to the more restrictive concept, while the inclusive concept remains unnamed (Anggoro et al., 2008). This study revealed that even at 9 years of age, English-speaking children were more likely to exclude plants from their classifications of entities that were 'alive' than their Indonesian-speaking counterparts.

Children's understanding of biological concepts reflects the acquisition and enrichment of content information as well as continuous reorganization of initial theories as children learn more about the biological world. Exploring the way in which infants progress from their initial knowledge base to more advanced understanding is another important piece of the puzzle.

Developing Scientific Processes Skills

In addition to children's understanding of scientific concepts in physical and biological sciences, children develop general science process skills from quite young ages. The popular phrase "scientist in the crib" (Gopnik et al., 2009) is used to describe infants' early science process skills, such as children's early explorations of cause and effect. More intentional process skills, the precursors to the foundational skills necessary in formal science, can be observed throughout early childhood. These include children's ability to recognize gaps

in their knowledge, to address these gaps through exploratory behavior and experimentation, and to analyze information and evidence to make conclusions (Jirout and Zimmerman, in press; Klahr et al., 2013). An important consideration in the development of these skills is *how* they develop, including methods used to this question.

The microgenetic approach provides many data points across trials during which performance changes and learning can be directly observed (Siegler and Crowley, 1991). This type of analysis can elucidate the underlying processes involved in learning a concept, which can then be targeted with instruction. The instructional methods most effective for developing these processes is a contentious area in the developmental and educational literature, with many factors to consider when determining how something should be taught. For example, Klahr and Chen's (2003) study of teaching children experimental design found that direct instruction of the content was most effective in children's learning, contrary to the push for 'discovery learning' in science education (see Chen and Siegler, earlier version of this article, for more detail). We extend the previous section on learning processes by discussing new methods of studying the development of scientific process skills, focusing on Bayesian Modeling and Cognitive Maps (Gopnik et al., 2004), and recent research addressing the issue of effectiveness of different pedagogical methods. We end with a brief discussion on the development of some specific science process skills.

Bayesian modeling uses children's prior knowledge or beliefs and the likelihood of different hypotheses to model learning (Perfors et al., 2011). It is thought to capture 'optimal inductive inference,' as well as making it possible to infer less than optimal ways that people think by comparing observed data to models (see Bayesian sections in the statistics chapters, or Perfors et al. (2011); for a nontechnical overview). Bayesian modeling has been successfully used to determine the processes behind children's understanding of causal mechanisms, and Bayes nets themselves have been used as a model of the processes by which children seem to infer causal relationships from evidence (Gopnik and Schulz, 2004). As an example, causal reasoning has been studied using a 'blicket detector,' a box that lights up and makes noise when different required actions and objects are used (Gopnik and Sobel, 2000). Gopnik and colleagues showed children a blicket detector that either did or did not light up when different configurations of objects were placed on it (Gopnik et al., 2001; Sobel et al., 2004). For example, children saw object *A* placed on the detector, and it lit up. It did not light up with object *B*, but did light up again when both *A* and *B* were placed on it. Children were told 'blickets' make the machine work, and were asked if each of the objects was a blicket. Children's causal inferences were similar to those generated with Bayes nets, considering the 'input,' or data children are given, and matched the predictive Bayesian models. Similarly, Xu and Kushnir (2013) and others suggest that infants demonstrate Bayesian-like inference during hypothesis testing, and Bayesian modeling has contributed to new knowledge about how children's scientific concepts develop in other domains as well.

In addition to using Bayesian models to study how development occurs, they have been informative for testing the effectiveness of pedagogical methods. Specifically, children seem to interpret types of instruction differently when forming theories that then influence learning behavior, with the different types of pedagogy influencing interpretation of the information provided. Bonawitz et al. (2011) observed preschool age children exploring a toy with four specific functions after being instructed to try and figure out how it works. When children were directly shown how the toy worked by demonstration of a single function, or saw another child receiving this demonstration, they explored for less time and discovered less novel functions than when they were not shown anything, or if the demonstrations they were shown were perceived as unintentional or incomplete. In a similar study, Buchsbaum et al. (2011) demonstrated several series of three actions on a toy, some of which included the same last two actions that resulted in music playing, some of which did not include these causal actions and did not result in music playing. When children perceived the person demonstrating the actions as teaching about the toy, they were less likely to discover the two-action cause of the music than children who thought the demonstrator was exploring the toy without knowing the underlying causal mechanism. Instead, they were more likely to directly imitate the actions, including the unnecessary third action in the sequence.

Consistent results have been found in other scientific domains as well. Fisher et al. (2013) found that in spatial learning, children learned shapes better with guided play than didactic instruction, though guided play also showed greater learning than free play. A possible explanation for these findings and several other similar findings in research on pedagogical effectiveness can perhaps be explained by Chi's (2009) theory that instruction is most effective when children are constructing evidence themselves, rather than participating or passively observing directed instruction, but learning is greatest when constructive activity is also *interactive*. This theory would suggest that instruction will be most effective in developing children's scientific concepts if it allows children to actively construct knowledge, but even further, to do so collaboratively or by some other interactive means. Further research is necessary to know what methods are most effective, and whether or not these results generalize across different learning domains. These studies suggest the importance of considering both learning goals and a teacher's knowledge base when planning pedagogical methods.

Another important aspect of early science learning and instruction is how to make the learning environment engaging. For children to learn in science, they must first be *curious* to learn something, and must recognize that there is something to be learned. Cognitive conflict, a strategy for inducing conceptual change, can lead to scientific curiosity (Klahr et al., 2013), or the desire to resolve uncertainty (Jirout and Klahr, 2012). In order for children to become curious, however, there must be some uncertainty or gap in their knowledge they wish to resolve. For example, in a study of children's exploration of causal relationships, Schulz and Bonawitz (2007) found that children preferred to explore a toy with an ambiguous causal mechanism over a novel toy, presumably to resolve the uncertainty presented by the ambiguity in the toy's function. Similar studies have found a consistent relationship with uncertainty or ambiguity and children's exploratory behavior, with an inverted U-shaped curve representing an 'optimal'

level of uncertainty that leads to exploratory behavior (Loewenstein, 1994; Litman et al., 2005), though this level appears to differ across individuals (Jirout and Klahr, 2012).

Question asking, a way children seek missing information (Kuhn and Dean, 2005), is both a foundational science process skill (NRC, 2012; Jirout and Zimmerman, in press) and a mechanism for learning science (Chouinard et al., 2007). Very young children are able to ask questions, with the majority of children's questions being identified as 'information seeking' rather than questions asking permission (e.g., Chouinard et al., 2007). Children's ability to ask *effective* questions, however, or those used to gain specific information necessary to resolve uncertainty, develops more slowly (King, 1991; Jirout and Klahr, under review). Kemler Nelson and colleagues have found that while 2- to 4-year-old children can ask topic-appropriate questions about artifact and animal functions, these questions often do not extend beyond seeking basic information of what something is called and what it does – lower level questions compared to more mechanistic ones necessary in science learning (Kemler Nelson et al., 2004; Greif et al., 2006). Asking questions, exploring, or experimenting provides children with information that they can then evaluate and use in terms of covariation as discussed above, in order to reason about causality and to revise or form theories.

The development of effective investigation through question asking or exploration is another area of continuous development, though, and is not very sophisticated in young children. For example, young children choose the better of two simple experiments in providing useful information, but are not very good at designing unconfounded experiments themselves until around third grade (Sodian et al., 1991; Piekny and Maehler, 2012) or even later (Bullock and Ziegler, 1999). Similar to their ability to reason about causal relationships in the studies discussed above, children can begin to use statistical information about covariance to reason and make conclusions from evidence, though this ability is limited by the complexity of the information children are given. In a simple study of a single cause, for example, children as young as 5 years can evaluate how evidence relates to a cause (Ruffman et al., 1993), and children as young as 4 years can predict how another person will change a prior belief with new covarying evidence (Koerberg et al., 2005). Preschool children were relatively good at drawing conclusions from perfect and partial covariation data (Piekny and Maehler, 2012), but even older children – 10–14 year olds – had difficulty interpreting noncovarying data (Kanari and Millar, 2004). Another source of difficulty for children is interpreting data that is inconsistent with their own beliefs, even with perfect covariation but especially with partial covariation (Koerber et al., 2005), though this finding is consistent with the performance seen in older children and even adults (Zimmerman and Croker, 2013).

Conclusion

In summary, research in recent decades has uncovered evidence that infants and young children may have considerably greater scientific knowledge at their fingertips than what was previously thought possible. Despite its early emergence, it is clear that this knowledge is far from complete. Although recent work has advanced our understanding of the complexities of scientific concepts in children, the conclusions drawn by Chen and Siegler 15 years ago still hold true today. Recent methodological advances, such as the use of computational modeling, allow new ways of exploring how different science knowledge is acquired. The growing literature on the understanding of conceptual domains across wide age ranges provides information about when children develop specific concepts, their ability to apply that knowledge to revise incorrect theories, the important role of language, and culture and experience in shaping scientific discovery. Findings on children's understanding of science concepts and how scientific reasoning develops have broad implications for education, including how different pedagogical methods might be most effective for learning in science.

Abstract

This article presents a synthesis of descriptive and instructional studies on the development of scientific concepts during childhood. Preschoolers' and young children's understandings of earth and space science concepts, physical science concepts, and life science concepts are described. Strategies to support the development of scientific understandings in young children are provided.

Children construct explanations about how things work in the natural world around them, and their ideas, in general, differ from scientifically accepted models. Researchers have used different terms including *naive ideas*, *alternative conceptions*, *misconceptions*, *preconceptions* and *initial explanatory frameworks* to describe children's alternative understandings. A considerable number of studies have been devoted to children's understandings of the natural world and changes that occur in these ideas as a result of development and/or instructional intervention (e.g., Baxter, 1989; Carey, 1985; Saçkes et al., 2010; Trundle and Saçkes, 2012; Vosniadou, 1994; Vosniadou and Brewer, 1992). Here, we present a synthesis of descriptive and instructional studies on the development of scientific concepts during childhood. We organized the information under four headings: earth and space science concepts, physical science concepts, life science concepts, and strategies to support the development of scientific understandings.

Children's Understanding of Earth and Space Science Concepts

Beginning with Piaget's pioneering studies, children's conceptual understandings of various earth and space science concepts have been reported in research literature. These studies mainly focused on children's understandings of scientific concepts targeted in elementary school and include weather phenomena, the night and day cycle, the shape of the earth, and moon phases.

Studies that examined children's understandings of the water cycle and related phenomena demonstrated that most young children believe that rain is water, that they tend not to relate clouds with rain, and that they also believe that rain simply falls from the sky (Saçkes et al., 2010). Young children tend to elucidate the mechanism of rainfall with an outside agent at early ages and they often attribute human characteristics to clouds and rain (Miner, 1992). Although most young children tend to pay attention to differences that occur in clouds when they change as a prelude to rain, many young children continue not to associate rain with clouds (Saçkes et al., 2010). They also have difficulty understanding the water cycle, possibly due to their poor performance on conservation and reversibility tasks, which encompass the process of rainfall (Bar, 1989). Not until the age of 9–10 years do children begin to appreciate the natural origin of clouds and consider clouds as a cause of rain as well as a sign of it (Bar, 1989; Piaget, 1972).

Many researchers believe that children's inability to explain the mechanism of rainfall is related to their lack of understanding of the major concepts of the water cycle, namely evaporation and condensation (Bar, 1989; Saçkes et al., 2010). Elementary school children start using the concepts of condensation and evaporation in describing the formation of clouds and rain (Moyle, 1980). However, many children, despite instruction, have difficulty understanding and explaining the role of condensation and evaporation in the formation of rain and clouds and in the water cycle process (Saçkes et al., 2010). Although the idea that rain comes from colliding clouds continue to be entertained by some children in late elementary grades, many children, as a result of schooling, begin to believe that rain falls when clouds become cold or heavy or when raindrops become heavy and fall (Bar, 1989; Saçkes et al., 2010). Children explain rain as water vapor all gathered up in clouds, but few children refer to changes in temperature as part of their explanation of how rain occurs and of the cyclic process that makes rain (Moyle, 1980).

The geographic location in which children live seems to influence their understandings of the mechanism of rainfall. Children from mountainous locations tend to have a better understanding of the water cycle than children from desert locations. They understand precipitation and condensation concepts significantly better than the children who live in deserts (Miner, 1992). This finding could be attributed to the fact that children in mountain environments tend to have richer experiences with the water cycle than children in desert environments. Thus, children who live in the mountains tend to understand the water cycle and related phenomena better than the children who live in deserts.

In addition to rainfall, Piaget also investigated children's understanding of the day and night cycle. Piaget (1972) reported that children perceive the day and night cycle as a result of the movement of the sun in the sky. Other studies reported similar findings – most young children attribute the day and night cycle to the movement of the sun in the sky or provide religious explanations for the phenomenon (Sharp, 1996). Vosniadou (1994) found that young children are likely to explain the day and night cycle with reference to their initial mental models, which probably form from their everyday experiences. Young children tend to think that the sun goes

down behind the mountains or that clouds cover up the sun, causing night. Older children construct a synthetic mental model by combining some scientific ideas with their initial models. Children who hold synthetic models tend to think that the sun and the moon revolve around the stationary earth every 24 h, or that the earth rotates in an up/down motion relative to the fixed positions of the sun and the moon on opposite sides of the earth.

Children's conceptions of the shape of the earth have been the focus of several studies. In their seminal work, Vosniadou and Brewer (1992) argued that most children consistently use a small number of well-defined mental models of earth to explain the appearance of the earth. Younger children tend to have a 'flat earth model' and they conceive of the earth as a rectangle or disc. While older children tend to have a 'spherical-earth model,' some children, however, maintain a combination mental model of a flat-and-spherical earth. This type of blended or combined model is called a 'synthetic mental model.' Three types of synthetic models were identified: the dual-earth model, the hollow-sphere model, and the flattened-sphere model. Children who hold to the dual-earth model believe that there are two earths – a flat one where people live and a round one up in the sky. Children with the hollow-sphere conceptual model believe that people live on the flat surface of the earth, which is located at the bottom of the spherical earth. Children who hold to the flattened-sphere model believe that the top and bottom of the earth are flat, and these are the places where people live.

Children's conceptions of the moon and observable changes in its appearance have also been examined in the literature. Studies demonstrated that most children, even at early ages, are aware that the appearance of the moon changes over time. Although most young children are aware that the appearance of the moon changes, they have a limited understanding about the pattern of this change (Piaget, 1972; Za'rour, 1976). Studies suggest that young children's interpretation of the changes in the moon's appearance differs with age. At early ages, children see human activity and supernatural forces as being responsible for the changes in the shape of the moon. Examples of their concepts include the notion that the moon is born or cut by people, or that fairies change the moon's appearance. Children also explain these changes via natural forces such as wind and clouds (Piaget, 1972; Haupt, 1950).

When children realize that changes in the moon are actually changes in the moon's appearance and not changes in the moon's size, they begin to construct a model to explain moon phases, based on the idea that something must be blocking either the sun's light from reaching the moon or the moon's light from reaching to the earth. Baxter (1989) reported four explanations that are based on this idea. Children believe that clouds, a planet other than earth, the sun, or the earth itself, cause moon phases by blocking the light. The idea that the shadow of the earth causes moon phases was reported as the most common explanation among the participants in Baxter's study. Indeed, this alternative concept, which is often called the 'eclipse model,' was reported as the most common alternative concept in the literature (Hobson et al., 2010; Trundle et al., 2002).

Children's Understanding of Physical Science Concepts

From infancy, children develop their own ideas and understandings of many physical phenomena. For example, children construct knowledge of force, heat, sounds, and states of matter (e.g., solids and liquids) early in life (Spelke, 1991). The development of infants' understanding of the physical world seems to be influenced by five major constraints: continuity, solidity, no action at a distance, gravity, and inertia (Spelke, 1991). 'Continuity' refers to an understanding that objects continue to exist and move on a connected path; 'solidity' implies that two objects cannot occupy the same place in a space at the same time; 'no action at a distance' suggests that objects travel independently in space unless they meet; 'gravity,' which is a force, causes objects to move downward when they are not supported; and 'inertia,' a property of matter, is the resistance of an object to change in its motion or state of rest (inactivity).

Studies suggest that infants as young as 3 months expect objects to move on a connected and unobstructed path. By the age of 6 months, infants develop an initial appreciation of gravity and inertia and they make valid inferences about the behavior of falling objects (Spelke, 1991). However, children often make miscalculations when falling objects are acted upon by outside forces. Bascandziev and Harris (2010), who used gravity tubes to describe preschoolers' misconceptions of gravity and free fall, described children's gravitational misconceptions as 'gravity error.' As with other misconceptions, they found that children had a hard time overcoming 'gravity error,' even after they experimented with materials and gathered empirical evidence of falling objects. Their research indicates that input from others, such as peers and teachers, has more influence on children's understandings of gravity-related concepts than their own evidenced-based observations. These findings hold widespread developmental implications for young children's science engagement and conceptual development.

Piaget (1971) described conceptions and learning progression about sound in children aged 4–8 years. He found that children aged 4–5 years believe that nothing passes between the object emitting a sound and the ear of the person who receives the sound, indicating that sounds need a clear unobstructed path in order to be heard. Six-year-old children believe that sounds stay within objects even if they are not heard. They conceive that sounds try to reach a person's ears, and when they cannot, the sounds return to the place/object where they originated. Beginning at age 7 years, children visualize sound as straight lines emanating in all directions (Piaget, 1971; Lautrey and Mazens, 2004). Results from more recent studies indicate that young children tend to attribute substantiality to sound and they think sound cannot pass through solids or liquids. When they experience that sounds can be heard through some solids, they conclude that the solids must include invisible holes through which the sound passes. Moreover, children believe that for sound to pass through a solid, the sound must be harder or stronger than the solid. These presuppositions were proposed to explain children's mental models related to permanence, continuity, and solidity (Mazens and Lautrey, 2003).

Results of studies demonstrate that even very young children understand that matter can break into tiny invisible pieces (i.e., molecules or ions of the substance) by dissolving (Nakhleh and Samarapungavan, 1999). Children understand that different substances or solutes dissolve differently, depending on the properties of the solution or solvent used for dissolving. Children tend to use a self-evident type of logic in explaining the properties of matter, and they construct ideas about different types and states of matter. Children tend to think of some solid matter with no visible granularity, such as wood and copper wire, as being continuous; whereas they recognize the particulate nature of solids that exist in small grains like sugar and table salt. Children also are more likely to recognize the particulate nature of liquids and gases rather than solids (Nakhleh and Samarapungavan, 1999). Piagetian theory supports children's responses when they distinguish between objects and matter itself. As children develop, they are more able to distinguish between the extensive and intensive properties of matter, and therefore discern between the matter and the object (Krnel et al., 2005). Very young children (aged 3 years) often classify matter on an item-by-item basis. Thus, they change their classification criteria with each new object. Even at the age of 7 years, children have difficulty grouping more than two items together, and color is the predominate grouping factor. By the age of 11 years, children use two or more factors when classifying matter – e.g., by substance (i.e., powders/solids/liquids) and by actions (i.e., how the items would be used). Even at this advanced developmental age, color remains an important factor in considering matter properties and groupings (Krnel et al., 2005).

Although the concepts of heat and temperature are separate entities, they are often taught together and used interchangeably in nonscientific dialogue. Even though these are everyday experiences, older students and adults alike have difficulty understanding thermal events and thermodynamics (Lewis and Linn, 1994). When considering issues of heat and temperature, very young children have difficulty using the particulate nature of matter to envision or explain the underlying scientific processes. The first mental models children hold, associate heat with burning or melting. However, these initial models do not describe the internal process. When asked why an object is melting, children may respond "because it is smaller" (Shayer and Wylam, 1981). Additionally, younger students often speak of heat in terms of being instantly created or destroyed, much like an object with an on/off switch (Albert, 1978). Albert found that the child's view changes to a more dynamic characterization of heat between the ages of 7 and 8 years. She also noted that children of this age begin to describe heat as a process. In her research, very young children did not discern between 'hot' and 'warm.' This distinction, including degrees of temperature, begins between the ages of 8 and 10 years. During this developmental stage, children begin to understand heat as an energy transfer (Albert, 1978). Children do not generally incorporate a caloric or kinetic view of heat until later in their development (Shayer Wylam, 1981). Similarities exist between 8-year-old children's conceptual organization of heat and sound. Lautrey and Mazen's (2004) study found the categories of explanation for sound (permanence, continuity, and solidity) were also applicable to children's mental models of heat. They found that children more often associated many trajectories (or paths) with heat than with sound. They theorized this difference to be due to the presence of many receptors for heat in the human body, whereas there are only two ears as primary receptors for sound. Thus, children can more easily observe heat in other objects, whereas the effects of sounds on objects cannot be readily observed (Lautrey and Mazens, 2004).

Students experience 'speed' or velocity from infancy. For example, children race on the playground, move from the path of a rolling ball, observe cars on the road, and comment on the 'fastness' of objects. Children, however, hold many naïve ideas regarding their everyday experiences with velocity. For example, young children often attribute closer objects as having higher speeds (Cross and Pithkey, 1988). Understanding the dynamic nature of motion is difficult for even high school children and some college students to achieve. Previously, students' understandings of motion were classified as either dynamic or nondynamic/direction-only. The dynamic view of motion includes the development of a Newtonian-like perspective. Dykstra and Sweet (2009) suggested a new classification of young students' views of motion, the 'snap-shot view.' With this view, children see that velocity varies at different times and that motion changes. The researchers' evidence suggests that speed differences are important aids to deepening children's understandings of force and motion. Results reported in the current literature are inconclusive and educators are uncertain if attaining a dynamic view of motion is a proper curriculum goal for fourth grade students. However, research results indicate that sixth grade students are able to achieve a dynamic view of motion, but they require more physical manipulation and experimentation than older students (Dykstra and Sweet, 2009).

The research literature also includes studies on children's understanding of force, another physical science concept. The results of these studies indicate that young children consider force to be a property of physical objects, and they relate force to the object's weight and size. Young children understand force to be something that is exerted only on heavy and big objects or something that is an internal property of physical objects. Researchers often describe these naive ideas as an 'internal force' model. By the age of 8–12 years the internal force model usually is replaced by another model called an 'acquired force' model. In this model, children only associate a force with an object when the object moves (Vosniadou, 1994).

Children's presuppositions influence how they understand the natural world. The following presuppositions seem to restrict children's understanding of the concept of force: (1) physical objects exist in the natural world, (2) these physical objects have properties, (3) force is a property of physical objects, (4) inanimate objects do not move by themselves, (5) the motion of inanimate objects requires an explanation, and (6) the explanation for movement of inanimate objects should be in terms of a causal agent (Vosniadou, 1994). These presuppositions influence children's interpretations of their everyday experiences, and they give rise to the following specific naive theories about force: (1) some objects respond to external actions upon them while others do not, (2) inanimate objects need to be pushed or pulled to move, and (3) inanimate objects stop moving by themselves (Vosniadou, 1994).

Researchers also have examined children's understanding of sinking and floating. Density and buoyancy are higher-order scientific ideas. A person must have foundational ideas about both matter and volume in order to scientifically understand density. Further complexity is added to this concept, because density is a property of substances but not necessarily of objects. Piaget, who provided the first framework for children's development with regard to density, labeled stages from stage 1 (ages 4–5 years) to stage 4 (age 12 years). Piaget claims that children at stage 4 are able to correctly explain how buoyancy correlates with relative weight, and they are able to understand mass per unit volume or density (1972). More recent studies demonstrate that preschoolers use their previous life experiences to predict which objects will float or sink and why. Children base their predictions on everyday experiences, explanations, on information they hear from adults, or they use a self-evident type of logic. Preschoolers usually explain flotation as being due to air inside an object, or they suggest that the weight of an object causes it to float, with lighter objects floating and heavier objects sinking. Children also use size and the substance of which the object is made to explain flotation, but they often conceive the size of the object to be synonymous with its weight (Havu-Nuutinen, 2005). What is known as the 'size-weight illusion' (i.e., believing that between two objects, the smaller object will be lighter when lifted) has been broadly represented in the research literature. Overcoming the size-weight illusion can be difficult for both older students and adults (Flanagan and Beltzner, 2000). Interestingly, children do not exhibit the 'size-weight illusion' until they are aged 4–5 years (Kohn, 1993).

Children's Understanding of Life Science Concepts

As with the physical and earth and space science concepts previously discussed, young children's ideas about living things differ from scientific norms (Piaget, 1972). Young children usually develop the alternative conception that an object moving in any way, such as rolling car, is alive. This conception becomes more sophisticated as children develop, and they begin to consider that only things that move on their own initiative are alive. Finally, at around the age of 10 years, children develop an understanding that animals and plants are alive, and many children at this age limit their thinking to only plants and animals. Children's initial ideas about living things may be attributed to their animistic thinking. For example, many young children believe plants are not alive, whereas they think the sun is alive because of the way it appears to move across the sky.

One source for children's animistic responses could be their poor knowledge of biology, which prevents them from including plants and animals together in a single category (Carey, 1985). According to Carey, children's understanding of biology undergoes a radical change between the ages of 4 and 10 years, and their early understandings of plants and animals can generally be described as anthropocentric (i.e., children use human beings as a reference to understand other living things).

Preschoolers usually do not assign typical animal properties to animals. For example, children tend to attribute eating and breathing only to humans and not to other animals. Older children, however, perceive the ability to eat and breathe as a distinguishing property of all animals (Carey, 1985). Preschoolers understand that living things, such as animals and plants, grow, whereas artifacts do not. Young children tend to be aware of animals' basic physiological needs, and they usually are aware of conditions that support animal and plant growth. While preschool children generally seem to be able to categorize living things, many also have difficulty identifying them as 'alive' (Backscheider et al., 1993). In other words, preschoolers tend to understand that plants and animals, like all living things, share some general basic properties (e.g., both plants and animals reproduce or make babies and they both grow). Despite this general knowledge, they still are unable to conclude that plants are living things. Young children seem to attribute intentional actions to animals but not to plants. Therefore, young children tend not to classify plants as living things. However, when preschoolers are taught that plants, like animals, are able to move in response to stimuli (e.g., phototropism where plants grow toward light and thigmotropism where plants move in response to touch) only then do they conclude that plants are alive. The concept that plants can move in goal-directed ways plays a more crucial role in the restructuring of children's ideas about what it means to be alive, than the understanding that plants need water and that they can grow (Opfer and Siegler, 2004).

Instructional Strategies to Support the Development of Science Concepts

Results from research studies demonstrate that alternative conceptions are often pervasive and resistant to change through traditional forms of instruction. Instructional strategies are more likely to be successful if they are specifically geared toward helping children restructure their existing conceptual understandings. These types of instructional strategies are based on conceptual change theory, and they usually involve the following elements in their designs: (1) take children's prior knowledge into consideration, (2) devise a learning environment to create cognitive conflict or dissonance, (3) support inquiry activities, (4) provide models and external representations of natural phenomena, (5) support the use and development of meta-conceptual awareness and strategy use, and (6) foster task-related motivational beliefs (Trundle and Saçkes, 2013).

Science education literature emphasizes inquiry-based instruction as one of the most effective ways to promote conceptual understandings of scientific phenomena (Trundle and Saçkes, 2012). Inquiry-based instruction includes hands-on activities with sense-making discussions and requires the active participation of learners. In such a learning environment, children are more likely to construct a scientific understanding of the targeted natural phenomena through restructuring of their existing alternative understandings (Anderson, 2002, 2007; Trundle et al., 2010). Children also have opportunities to develop inquiry skills (e.g., observing, inferring, posing questions, forming hypotheses, and developing conclusions based on the analysis of data) (Anderson, 2007).

Several forms of inquiry-based instruction have been developed and described in the literature, such as the 5E learning cycle, the predict-observe-explain model, and the

preschool learning cycle. These models have been developed as both theoretical and practical answers to developmentally appropriate classroom implementations. Bybee's 5E learning cycle consists of five phases: engagement, exploration, explanation, elaboration, and evaluation (Trowbridge and Bybee, 1996). The 5E cycle emerged from Piagetian theory; through the exploration phase, children experience assimilation and/or disequilibrium. Children then make accommodations and organize in the explanation and elaboration phases respectively (Tobin et al., 1994). This 5E learning cycle was developed for the elementary classroom with young children's capabilities in mind.

The predict-observe-explain (POE) model, by White and Gunstone (1992), developed as a way to discover the individual student's predictions regarding a specific event, and the reasoning behind these predictions. Besides noting children's preconceptions, the POE model also provides teachers with useful information regarding children's thinking. The model enhances student engagement, discussion, and the generation of follow-up investigations (Hsu et al., 2011).

The preschool learning cycle (Trundle et al., 2013) integrates Bybee's effective 5E learning cycle with the developmental needs of the youngest learners in preschool. The three-part cyclical process starts with play, progresses to exploration, and is followed by discussion. This cycle includes hearts-on, hands-on, and minds-on learning. During the hearts-on phase, the teachers tap into the children's curiosities and link their prior knowledge with the new material. Children are given opportunities during the hands-on phase to interact with the materials in new and different ways. Finally, teachers provide age-appropriate labels or scientific terms to the learning process during the minds-on phase. Teachers can implement this model to connect to very young children's interests and foster their scientific explorations (Trundle et al., 2012).

One instructional strategy, a project approach, successfully incorporates inquiry into the teaching of science concepts. This approach engages children with in-depth investigations into science concepts that are of interest to them. Children ask questions or define problems, use tools to collect and analyze data, and produce artifacts to communicate and present their understandings. They answer questions they themselves posed or solve problems that they defined. The project approach incorporates three phases: phase 1, beginning a project; phase 2, developing the project; and phase 3, concluding the project. In each of the phases, the students move through five exercises: discussion, fieldwork, representation, investigation, and display (Katz and Chard, 2000). Teachers can use this approach to scaffold developmentally appropriate projects into their curricula (Chard, 1998; Helm and Katz, 2010; Katz, 1994).

Some researchers argue that inquiry-based instructional approaches place a heavy cognitive load on learners, especially younger children who have little cognitive processing capacity, and thus discourage children from processing novel information and restructuring their conceptual understandings (Hobson et al., 2010; Kirschner et al., 2006; Mayer, 2004). Therefore, inquiry-based instructional approaches must involve developmentally appropriate structuring and scaffolding for young children (Trundle and Saçkes, 2012). For example, guided inquiry, with an appropriate level of scaffolding and guidance in formulating research questions and procedures, should be used in early childhood classrooms rather than open inquiry where children, on their own, formulate research questions as well as procedures to answer them. Teachers can reduce the level of guidance as children develop expertise in the targeted domain, and as they age, develop, and move into the upper grades (Bell et al., 2005; Banchi and Bell, 2008).

Scientific Controversies

Trevor Pinch, Cornell University, Ithaca, NY, USA

Abstract

This article examines the research on scientific controversies, largely carried out within the field of science and technology studies (STS). It identifies different strands of research including priority disputes, controversy as a method, controversies to do with the impact of science and technology on society and controversies at the research frontiers of science. It concludes by arguing that within modern STS the boundary between studying controversies within science and how they ramify in the wider society has largely been dissolved.

There is a long history of studying scientific controversies within the sociology of science. Different sorts of controversy and different approaches to analyzing them have emerged over the years. Here, I summarize the main developments.

Priority Disputes

The first type of controversy to gain attention within the sociology of science was the 'priority dispute.' This is a dispute between one or more scientists or groups of scientists who claim 'priority' for a scientific discovery. In other words, there are claims and counterclaims as to who has first made a particular discovery. The reason scientists care so much about priority was first pointed out by Robert Merton (1957). He argued that the main reward in science is recognition, bestowed in prizes and the naming of discoveries. In other sorts of endeavors, for instance, technological invention, rewards take other forms, such as patent rights or money.

Priority disputes in science are frequent occurrences because science as an activity builds upon previous knowledge and techniques that are widely disseminated and shared within the scientific community. This means that scientists, who often work within what Thomas Kuhn (1962) has called a shared paradigm, are solving similar sorts of puzzles and this will lead to disputes as to who first arrived at a particular solution. New instruments and techniques, which enable new discoveries, are also collectively shared. Discoveries are, thus, very much in the air. Often scientists are aware that they are in a race and who their main 'competitors' are. During such races, the norms of sharing data, techniques, and knowledge may break down, and such races can be accompanied by acrimonious accusations of breaches of correct scientific behavior, such as occurred during the race to discover the structure of DNA, where Watson and Crick were accused of stealing Rosalind Franklin's X-ray crystallography results (Sayre, 1975).

Merton's interest in priority disputes stemmed from his claim that science has a particular normative structure or 'institutional ethos' with an accompanying set of rewards and sanctions. Because so much of the reward structure of science is built upon recognition for new discoveries, scientists are particularly concerned to establish priority for their findings. Priority disputes are legion, such as the famous fight between Newton and Leibnitz over who first discovered the calculus, or the more recent fight between the French, Institute Pasteur group, and the American researcher, Robert Gallo, over who first established HIV as the cause of AIDS. In this case there was not only scientific priority at stake, but also the licensing of the lucrative blood test for identifying AIDS. The controversy could only be settled by intervention at the highest political level. The Presidents of the U.S. and France, Ronald Reagan and Jacques Chirac, agreed to share the proceeds from the discovery. This case was marked by additional controversy because of allegations of scientific misconduct raised against Gallo, which led to Congressional and National Institute of Health (NIH) investigations. It was one of the first times in science that a controversy was settled by politicians. The AIDS priority dispute reminds us that the notion of a 'community of scientists' characterized by internal struggles for recognition does not fit science in the latter part of the twentieth century. Scientists in areas such as biotechnology increasingly move between academia and start-up companies, and seek both reputational and financial recognition through stock options and the like (Shapin, 2008).

Thomas Kuhn (1962) raised a fundamental problem for the analysis of priority disputes. A priority dispute is predicated upon a model of science, known as the 'point model' of scientific discovery, which can establish unambiguously *who* discovered *what* and *when*. Asking the question who discovered oxygen, Kuhn showed that the crucial issue is what counts as oxygen. If it is the dephlogisticated air first analyzed by Priestly then the discovery goes to him, but if it is oxygen as understood within the modern meaning of atomic weights, then the discovery must be granted to Lavoisier's later identification. The 'point model' requires discovery to be instantaneous, and for discoveries to be recognized and dated. A rival 'attributional model' of discovery, first developed by Augustin Brannigan (1981), draws attention to the social processes by which scientific discoveries are recognized and 'attributed.' This approach seems to make better sense of the fact that what counts as a discovery can vary over time. In short, it questions the Eureka moment of the point model. Woolgar (1976), in a pioneering analysis of the discovery of pulsars, showed that the date of the discovery varies depending on what stage in the process is taken to be the defining point of the discovery. If the discovery is the first announcement of 'scruff' by Jocelyn Bell, a graduate student in Anthony Hewish's investigative team, when examining a chart recording of signals from the radio telescope, then it will be dated earlier than when it was realized

following extensive investigations that the unambiguous source of this 'scruff' was a distant and novel kind of astrophysical source. This case was particularly controversial because it was alleged by the dissonant Cambridge radio astronomer Fred Hoyle that the Nobel Prize winners for this discovery should have included Jocelyn Bell. Priority disputes can thus touch on the social fabric of science, such as its gender relationships and hierarchical structure.

The point model of discovery is embedded in the reward system of science. For example, most significant rewards accrue to the scientist or group who is 'first past the post.' Interestingly with modern discovery claims posted to the Internet, the exact date and time when a paper is first posted becomes even more crucial in establishing priority.

Controversy as a Method

Controversies as a form of method became important in the sociology of scientific knowledge (SSK) in the 1970s and 1980s. SSK went on to replace the earlier Mertonian sociology of science with its focus upon the rewards and institutions of science. For SSK researchers and for other strands within the emerging field of Science and Technology Studies (STS), such as feminist science studies (Haraway, 1989), it has been important to study moments of contention in science. It is during such moments that the often invisible processes of the working of science become more visible and hence available to analysis.

One metaphor for understanding the methodological importance given to controversies is that of 'punching' a system. Scientists on occasion gain insight into natural systems by punching them. For example, one may learn more about the laws of momentum by bouncing one billiard ball off another than by watching a stationary billiard ball. Similarly, Rutherford famously used scattering experiments in which gold foil was bombarded with alpha particles to uncover the structure of the atom and, in particular, the presence of the nucleus. In sociology, a similar methodology was advocated by Harold Garfinkel, for investigating the taken-for-granted features of social life. His breaching experiments involved breaking or breaching some taken-for-granted social convention, say, in routine greetings. The methodological assumption underpinning the study of controversies is similar, only in this case the breach in the normal social operation of science is produced by the scientists themselves. By studying a scientific controversy, or moments of contestation, one learns something about the underlying dynamics of science and its relations with wider society. For instance, during a controversy the normally hidden social dimensions of science (including its gender biases) may become more explicit. Sites of contestation are places to facilitate the investigation of, for instance, the metaphors, assumptions and political struggles embedded within science (or for that matter, technology and medicine).

Three Strands of Controversy Research

One can identify three broad strands of research on controversies within STS. The first approach, which dates back to the 1960s, was concerned largely with controversies provoked by contemporary science and technology and what was perceived to be its increasingly deleterious impact on the wider society. The controversies often crystallized around particular technologies such as nuclear power, pesticides and agribusiness in general, or technologies used in warfare, such as Agent Orange, or the perceived threat of what was then called 'genetic engineering.' Often groups of concerned citizens and scientists organized to oppose such technologies – for example, Rachel Carson's warnings about the dire effects of pesticides in her book *Silent Spring*. The source of controversy was the perceived negative impact of science and technology on particular groups and it is the study of these political responses that forms the core of the analysis.

The second strand is the study in the 1970s and 1980s of controversies *within* science. This was briefly mentioned above and emerged as part of SSK and its attempts to study how scientific knowledge is 'socially constructed.' By focusing on controversies at the research frontier of science, scholars were able to delineate what was at stake for groups of scientists as they fought over very specific knowledge claims, such as the existence of a new room-temperature form of nuclear fusion known as 'cold fusion,' or whether particular experimental results in physics had been replicated or not (Collins, 1992 [1985]). This approach was also extended into technology by what has been called the study of technoscience (Latour, 1987), and by the Social construction of technology (SCOT) (Bijker et al., 2013[1987]).

The third strand of controversy studies can be thought of as a merger of the earlier two strands (and is discussed at greater length in the final section of this article). Within contemporary STS, many researchers follow scientific controversies wherever they ramify. In other words, they make less of a distinction between controversies within science and those that impact the wider society. Modern scientometric tools sometimes help analysts to follow or map such controversies and the many different participants who may be scattered globally.

Controversies over the Impact of Science on Society

Many of the controversies over science and society that dominate today – such as global warming, sustainable energy, environmental degradation, and biomedical interventions into life – have their roots in earlier debates in the 1960s. The Vietnam War protests, the emergence of the counterculture, and the civil rights movement, formed part of a wider backdrop against which science and technology increasingly came into question. The political protest movements of the 1960s, followed by the environmental movement in the 1970s, led to recognition that science and technology are neither neutral nor necessarily beneficial, and that many developments stemming from modern science and technology, such as nuclear power, the petrochemical industries, and genetic engineering, raise profound and controversial issues for a concerned citizenry.

Dorothy Nelkin, a pioneer in analyzing these types of dispute, identified a range of different sorts of political, economic, and ethical controversies that engaged the public (her research was almost exclusively based in the United States (Nelkin, 1995)). Early research by Nelkin and her colleagues focused mainly on the interest politics of the groups involved

(Nelkin, 1992): how and why they got involved in political action over science and technology; their underlying political values; and how effective they were. Participants' positions in controversies were taken to be consistent with their interests, although these interests were not necessarily determinate in bringing about closure. For instance, the demise of nuclear power in the United States had as much to do with economics as with political protest.

Since scientists themselves often played an active part in these disputes, part of the analysis touched upon how scientists deployed their specialized knowledge for political aims. By and large, this research tradition avoided using the entry of scientists into these disputes as an opportunity to examine the core processes of knowledge construction. In short, the attention was focused upon seeing how scientists became political rather than upon how politics might itself shape scientific knowledge. Political controversies were treated as analytically separable from epistemic controversies and as resolved by distinct processes of closure (Engelhardt and Caplan, 1987). Typically epistemic controversies were thought to be closed through the application of epistemic and methodological standards, while political controversies were closed through the intervention of 'nonscientific factors,' such as economic and political interests.

Controversies at the Research Frontiers of Science

The SSK, which emerged in the late 1970s, was concerned to examine how scientific knowledge itself was socially shaped or constructed. A key tenet of this new sociology of science, as formulated by David Bloor (1991[1976]) in his 'Strong Program,' was that of symmetry. This principle called upon sociologists to use the same explanatory resources to explain both successful and unsuccessful knowledge claims. This was a way to avoid a sociology of error whereby the social would be evoked to explain false knowledge, leaving true knowledge as simply revealed, or generated by some universal epistemological principle or rule of method. Controversies at the research frontiers over knowledge claims were good places to carry through the principle of 'symmetry.' With each side in a dispute claiming to have 'truth on its side,' and disparaging the efforts of the other, and with the very outcome of the controversy still unknown, there was less temptation to carry out a sociology of error. Full-blooded sociological explanations as to how credibility and trust were gained, maintained, and lost could be mounted. Unlike the approach to controversies on the impact of society favored by Nelkin, the very scientific claims made by the participants became subject to analysis.

Bloor and his colleagues in what was known as the 'Edinburgh School' pursued their program mainly through theoretical analysis supported by historical case studies (an exception was the work of Andy Pickering who studied contemporaneous controversies in particle physics). Collins and the 'Bath School' by contrast, developed an empirical method for studying the SSK in contemporaneous cases – a method based primarily upon the study of scientific controversies (Collins, 1992[1985]; Pinch, 1986; Collins and Pinch, 1998). Generalizing from several case studies of controversies, Collins (1981) argued that during controversies scientific findings exhibited 'interpretative flexibility,' with the facts at stake being debated and interpreted in radically different ways by the parties in the controversy. This interpretative flexibility did not last forever. By following a controversy over time researchers could delineate the process of 'closure' by which controversy vanished and consensus emerged. Collins defined the group of scientists involved in a controversy as the 'core set.' Only a very limited set of scientists actively partook in controversies, the rest of the scientific community depended upon the core set for their expert judgment as to what to believe.

Following controversies from their inception to the point of closure, allowed researchers to better understand 'science in the making' (Latour, 1987). Controversies when seen through the sociological lens turned out to be messy things and were very rarely resolved by experiments alone. Collins (1992[1985]) developed the notion of an 'experimenter's regress' to explain the lack of compulsion of experiments during controversies.

Often the losing side in a scientific controversy continues to fight for its position long after the consensus has turned against it. Those who continue to fight the good fight meet increasing disapprobation from their colleagues and may be forced to leave science altogether. 'Life after death' for discredited phenomena such as cold fusion goes on at the margins and often finally passes away only when the protagonists themselves die or retire (Simon, 2002). Sometimes scientists caught up in scientific controversies who find themselves on the losing side enter into an explicit form of scientific 'dissent,' which can involve them in attempts to form new alliances between academic institutions, interest groups, and the public (Martin, 1991, 1998; Delborne, 2008: 514). Opposition *outside* science to particular theories *in* science (e.g., Darwin's theory of evolution, or Einstein's theory of relativity) also presents a continuing source of controversy (Wazeck, 2013).

Powerful actors with vested political interests, such as the tobacco lobby in the United States, have latched onto the idea of scientific controversy as a way of fighting a scientific consensus that is moving against them. By raising issues of doubt and uncertainty over knowledge claims, thus setting the stage for a faux scientific controversy, over, say, the health hazards of smoking or the thesis that global warming is produced by human activities, such actors can resist the prevailing consensus (Oreskes and Conway, 2010).

The uncertain side of science is clearest during moments of controversy and it has been argued that teaching science through controversies is good way to give students a more realistic idea of scientific practice. Most scientists never experience controversies directly, and often it is those further from the research frontier who have a firmer sense of the robust nature of scientific method and the certainty of experimental results. This 'distance lends enchantment' phenomenon (Collins, 1992[1985]) has been expressed by MacKenzie (1990) for technology in terms of a 'certainty trough' whereby people closest to a technology and those furthest away from it both experience the most uncertainty about a technology's working than those at middle distance. Returning to science, after exposure to a controversy, scientists often become more aware of the social side of science and start to read in science studies and even employ ideas drawn from science studies to understand what has happened to them.

The sociological approach to controversies has also been taken up by historians (e.g., Rudwick, 1985). Such studies pose

particular methodological challenges because often the viewpoint of the losing side in a controversy has vanished from history (Dascal, 1998). Shapin and Schaffer's (2011[1985]) study of the dispute between Robert Boyle and Thomas Hobbes over Boyle's air-pump experiments was a landmark in research on scientific controversy, because it showed how the wider political climate, in this case that of Restoration Britain, could shape the outcome of a controversy and at the same time help institutionalize a new way of fact-making – the experiment – in the Royal Society. It also drew attention to the literary and technological dimensions of building factual assent in science. By documenting the witnesses to particular experimental performances a culture of 'virtual witnessing' was born.

The SSK approach to scientific controversy has also been influential in the study of technology. The SCOT framework uses concepts imported from the study of scientific controversy such as 'interpretative flexibility' and 'closure.' A variety of competing meanings are found in technological artifacts and scholars study how 'closure mechanisms' produce a stable meaning of a technology (Pinch and Bijker, 1984; Bijker, 1995).

Another influential SSK approach to the study of scientific and technological controversies has been that developed by Bruno Latour and Michel Callon. Actor-Network Theory, as it has become known, has taken on a life of its own and has gone through several reiterations. The seminal work in the 1980s formed an important strand to the SSK approach toward controversies. Callon's article on a controversy over a new method of harvesting scallops in France argues that the outcome of the controversy cannot be explained by reference to the social realm alone, because the analyst must also take account of the actions of nonhuman actors, such as scallops and ocean currents (Callon, 1986). Subsequently Latour's work on how 'trials of strength' are settled in science and technology has become especially influential. Such struggles, according to Latour (1987), involve aligning sociotechnical resources into so-called 'immutable mobiles' or black boxes: objects that remained fixed when transported along scientific networks and which contain embedded within them sets of social and material relationships.

One of the key ideas in all controversy research carried out within SSK is the notion that science has moments of openness or uncertainty followed by closure. Once a matter of fact is settled or black boxed, it is very hard to reopen the black box (Pinch, 1986; Latour, 1987). Often, these processes of closure are woven into the fabric of scientific practices and one can observe the closure or black boxing processes *in situ*. It is at this point that controversy research meets another very influential tradition within SSK known as Laboratory Studies (Lynch, 1993). For instance, Latour and Woolgar (1986[1979]) in their now classic study of a molecular biology laboratory observed scientific practices close up but also had access to a controversy in the lab. They were able to show how literary inscriptions played a special role as a marker in settling controversies. Controversies could be analyzed in terms of whether certain modalities are added to or subtracted from scientific statements making them more or less factlike. This enables the STS analyst to follow the opening and closure of a controversy and to examine how previously resolved controversies become embedded within taken-for-granted results, theories, and techniques.

A detailed examination of the role of discourse in scientific controversies was carried out by Gilbert and Mulkay (1984). They showed how particular discursive repertoires were used selectively by scientists in order to bolster their own claims or undermine those of their opponents. Subsequently, there has been much work on how a variety of rhetorical, visual, and textual resources operate during controversies (e.g., Lynch and Woolgar, 1990; Myers, 1990; Pinch, 1996). Sometimes the resolution of a controversy is only possible by drawing boundaries around the relevant experts who can play a role in the controversy. Sometimes particular scientific objects cross such boundaries and form a nexus around which a controversy can be resolved. Such 'boundary work' (Gieryn, 1983) and 'boundary objects' (Star and Griesemer, 1989) form another important analytical resource for understanding how controversies develop and are brought to closure.

Scientific Controversy in STS Today

The earlier distinction between controversies in science and those over the social impact of science of technology has largely been dissolved in contemporary STS. Another way of putting this is to say that in contemporary work the sites of contestation chosen for analysis have become more heterogeneous. Part of the reason for this heterogeneity is that increasingly the boundaries around expertise have become much harder to delineate (Collins and Evans, 2007). There is no longer assumed to be a one-to-one mapping between expert authority and expert credentials and this means that lay people and activists can themselves acquire sufficient expertise to engage scientists on their own terms (Wynne, 1989). In his well-known case study, Steven Epstein (1996) showed how AIDS activists, for instance, managed to reconfigure some of the science of clinically controlled trials of AIDS drugs.

In addition, the relationship between analyst and actor in controversy research has increasingly been problematized (Ashmore and Richards, 1996). Reflexivity is sometimes embraced by analysts who even become occasional participants in the controversies they study. The study of controversies in modern technoscience – with its porous boundaries between science, technology, politics, the media, and the citizenry – also calls for the analyst to adopt a broader array of analytical tools. With the growing role played by the media, there is also more attention upon the role of audiences for specific controversies (e.g., Delborne, 2011).

Although the fundamental insights provided by SSK remain influential, such insights are supplemented by an increased understanding of how macropolitical structures, such as the state and the legal system, enable and constrain the outcome of scientific controversies. Within the radical agenda of ANT and its sociology of associations, the very distinction between macro and micro is itself dissolved (Latour, 2005). The tools available to study controversies in contemporary science and technology have also expanded. There are several groups involved in a project initiated by Bruno Latour on 'mapping scientific controversies.' In this project, controversies are defined in the constructivist sense as "every bit of science and

technology which is not yet stabilized, closed or 'black boxed'" (Venturini, 2010). This project on the cartography of controversies is heavily influenced by ANT and has evolved several Web-based scientometric tools for following controversies, although face to face interactions still form an important part of the analysis (Venturini, 2012).

Contemporary research into controversies draws upon the lessons of constructivist SSK in not taking for granted that claims are settled by epistemic or methodological fiat. The movement from openness to closure involves deploying a whole range of resources. Such work also pays close attention to how actors themselves describe the situations they face. But with the move to study sociotechnical controversies in wider society, the sorts of actors dealt with are likely to be much more heterogeneous. The 'core set' idea of a bounded community of scientists who conduct the controversy still works for the study of controversies within the more esoteric districts of science, but analysts these days are more likely to embrace the key ANT idea that controversies ramify endlessly, especially when the wider sociotechnical assemblage is studied.

Controversies involving science and technology are today examined in the courtroom, in the media, in quasigovernmental policy organizations, in the state and its security apparatus, and in citizen action groups. A controversy or hot spot may be sparked by almost anything, such as the testing of a new drug, or a claim made about a new smart phone, or a natural (though possibly human-caused) calamity such as the collapse of the honey bee population (Suryanarayanan and Kleinman, 2013). There has been particular interest in controversies involving health and medicine, such as contentious new disease categories (Murphy, 2006), and in the activities of patient activist groups (Silverman, 2013). The strong feminist tradition in science studies has continued with, for instance, research on male contraceptives (Oudshoorn, 2003). Wherever there are sociotechnical disputes – such as, for instance, in mapping the state (Carroll, 2006; Leuenberger and Schnell, 2010) – one can study the movement between openness and closure as powerful social choices get embedded within material structures and procedures. Controversy research has largely been located in the US and Europe but researchers today increasingly explore controversies in the Global South. Controversy research is a taken-for-granted part of STS, and that is testament to its success as a method.

Abstract

The scientific discipline, as the primary unit of internal differentiation of science, is an invention of nineteenth century society. There exists a long semantic prehistory of *disciplina* as a term for the ordering of knowledge for purposes of instruction in schools and universities. But only the nineteenth century established real disciplinary communication systems. They are based on specialization of scientists, role differentiation in the organizations of science, the emergence of standard forms of scientific publication, and the rise of the research imperative which demands an incessant search for novelties. All these structural changes coalesce in the disciplinary community as a new type of communication system in science. After that the discipline functions as unit of structure formation in the social system of science, in systems of higher education, as a subject domain for teaching and learning in schools, and finally, as a designation of occupational and professional roles. Although the processes of differentiation in science have been going on ever since, the scientific discipline as a basic unit of structure formation is stabilized by these plural roles in different functional contexts of modern society. Finally, the individual discipline is embedded in an internal environment of other disciplines. The continuous mutual observation and interaction of these disciplines is the most important factor in the dynamics of modern science.

The scientific discipline as the primary unit of internal differentiation of science is an invention of nineteenth century society. There exists a long semantic prehistory of *disciplina* as a term for the ordering of knowledge for the purposes of instruction in schools and universities. But only the nineteenth century established real disciplinary communication systems. Since then the discipline has functioned as a unit of structure formation in the social system of science, in systems of higher education, as a subject domain for teaching and learning in schools, and finally as the designation of occupational and professional roles. Although the processes of differentiation in science are going on all the time, the scientific discipline as a basic unit of structure formation is stabilized by these plural roles in different functional contexts in modern society.

Unit Divisions of Knowledge

Disciplina is derived from the Latin *discere* (learning), and it has often been used since late Antiquity and the early Middle Ages as one side of the distinction *disciplina* vs. *doctrina* (Marrou, 1934). Both terms meant ways of ordering knowledge for purposes of teaching and learning. Often they were used synonymously. In other usages *doctrina* is more intellectual and *disciplina* more pedagogical, more focused on methods of inculcating knowledge. A somewhat later development among the church fathers adds to *disciplina* implications such as admonition, correction, and even punishment for mistakes. This concurs with recent interpretations of discipline, especially in the wake of Michel Foucault, making use of the ambiguity of *discipline* as a term always pointing to knowledge and disciplinary power at the same time (cf. Hoskin in Messer-Davidow et al., 1993). Finally, there is the role differentiation of teaching and learning and the distinction *doctrina/disciplina* is obviously correlated with it (Swoboda, 1979).

One can still find the same understandings of *doctrina* and *disciplina* in the literature of the eighteenth century. But what changed since the Renaissance is that these two terms no longer refer to very small particles of knowledge. They point instead to entire systems of knowledge (Ong, 1958). This goes along with the ever more extensive use by early modern Europe of classifications of knowledge and encyclopedic compilations of knowledge in which disciplines function as unit divisions of knowledge. The background to this is the growth of knowledge related to developments such as the invention of printing, the intensified contacts with other world regions, economic growth and its correlates such as mining and building activities. But in these early modern developments there still dominates the *archival function of disciplines*. The discipline is a place where one deposits knowledge after having found it out, but it is not an active system for the production of knowledge.

Disciplines as Communication Systems

A first premise for the rise of disciplines as production and communication systems in science is the specialization of scientists and the role differentiation attendant on it (Stichweh, 1984, 1992). Specialization is first of all an intellectual orientation. It depends on a decision to concentrate on a relatively small field of scientific activity, and, as is the case for any such decision, one needs a social context supporting it, that is, other persons taking the same decision. Such decisions are rare around 1750 when encyclopedic orientations dominated among professional and amateur scientists alike, but they gained in prominence in the last decades of the eighteenth century. Second, specialization as role differentiation points to the educational system, which is almost the only place in which such specialized roles can be institutionalized as occupational roles. From this results a close coupling of the emerging disciplinary structures in science and the role structures of

institutions of higher education. This coupling is realized for the first time in the reformed German universities of the first half of the nineteenth century and afterwards quickly spreads from there to other countries. Third, role differentiation in institutions of higher education depends on conditions of organizational growth and organizational pluralization. There has to be a sufficient number of organizations which must be big enough for having differentiated roles and these organizations must be interrelated in an ongoing continuity of interactions.

The emergence of *communities of specialists* is a further relevant circumstance. In this respect the rise of disciplines is synonymous with the emergence of *scientific communities* theorized about since Thomas Kuhn (Kuhn, 1970). Scientific communities rest on the intensification of interaction, shared expertise, a certain commonality of values, and the orientation of community members towards problem constellations constitutive of the respective discipline. Modern science is not based on the achievements of extraordinary individuals but on the epistemic force of disciplinary communities.

Scientific communities are *communication systems*. In this respect the emergence of the scientific discipline is equivalent to the invention of new communication forms specific of disciplinary communities. First of all one may think here of new forms of *scientific publications*. In the eighteenth century a wide spectrum of publication forms existed; they were not, however, specialized in any way. There were instructional handbooks at the university level, journals of a general scientific nature for a regional public interested in utility, and academy journals aiming at an international public, each covering a wide subject area but with rather limited communicative effects. It was only after 1780 that in France, in Germany, and finally, in England, nationwide journals with a specific orientation on such subjects as chemistry, physics, mineralogy, and philology appeared. In contrast to isolated precursors in previous decades, these journals were able to exist for longer periods exactly because they brought together a *community of authors*. These authors accepted the specialization chosen by the journal; but at the same time they continually modified this specialization by the cumulative effect of their published articles. Thus the status of the scientific publication changed. It now represented the only communicative form by which, at the macrolevel of the system of science – defined originally by national but later by supranational networks – communication complexes specialized along disciplinary lines could be bound together and persist in the long run (Stichweh, 1984, Chap. 6, Bazerman, 1988).

At the same time the scientific publication became a formal principle interfering in every scientific production process. Increasingly restrictive conditions were defined regarding what type of communication was acceptable for publication. These conditions included the requirement of identifying the problem tackled in the article, the sequential presentation of the argument, a description of the methods used, presentation of empirical evidence, restrictions on the complexity of the argument accepted within an individual publication, linkage with earlier communications by other scientists – using citations and other techniques – and the admissibility of presenting speculative thoughts. In a kind of feedback loop, publications, as the ultimate form of scientific communication, exercised pressure on the scientific production process (i.e., on research) and were thereby able to integrate disciplines as social systems.

This reorganization of the *scientific production process* adheres to one new imperative: the *search for novelties*. The history of early modern Europe was already characterized by a slow shift in the accompanying semantics associated with scientific truth, from an imperative to preserve the truth to an interest in the novelty of an invention. The success achieved in organizing traditional knowledge, as well as tendencies towards empirical methods and increased use of scientific instruments, worked toward this end. In this dimension, a further discontinuity can be observed in the genesis of the term *research* in the years after 1790. In early modern times the transition from the preservation to the enlargement of knowledge could only be perceived as a continual process. In contrast, *research* from about 1800 refers to a fundamental, and at any time realizable, questioning of the entire body of knowledge until then considered as true. Competent scientific communication then had to be based on research in this sense. What was communicated might be a small particle of knowledge, as long as it was a new particle of knowledge. Scientific disciplines then became research disciplines based on the incessant production of novelties.

The link between scientific disciplines and organizations of higher education is mediated by two more organizational structures. The first of these are *disciplinary careers*. Specialized scientists as members of disciplinary communities do not need only specialized occupational roles. Additionally there may be a need for careers in terms of these specialized roles. This again is a condition which sharply distinguishes eighteenth from nineteenth century universities. Around 1750 you still find, even in German universities, hierarchical career patterns which implied that there was a hierarchical succession of chairs inside of faculties and a hierarchical sequence of faculties by which a university career was defined as a progression of steps through these hierarchized chairs. One could, for example, rise from a chair in the philosophical faculty to an (intellectually unrelated) chair in the medical faculty. The reorganization of universities since early nineteenth century completely discontinued this pattern. Instead of a succession of chairs in one and the same university, a scientific career meant a progression through positions inside a discipline, which normally demands a career migration between universities. This presupposes intensified interactions and competitive relations among universities which compete for qualified personnel and quickly take up new specializations introduced elsewhere. In Germany such regularized career paths through the national university system were especially to be observed from around 1850.

This pattern is again closely related to *disciplinary curricula*, meaning that one follows one's disciplinary agenda not only in one's research practice and personal career, but furthermore that there exist institutional structures favoring teaching along lines close to current disciplinary core developments. The unity of teaching and research is one famous formula for this, but this formula does not yet prescribe disciplinary curricular structures which would demand that there should be a complete organization of academic studies close to the current intellectual problem situation and systematics of a scientific discipline. Only if this is the case does there arise a *professionalization of a scientific discipline*, which means that

a systematic organization of academic studies prepares for a non-academic occupational role which is close to the knowledge system of the discipline. Besides professionalization there is then the effect that the discipline educates its own future research practitioners in terms of the methods and theories constitutive of the discipline. A discipline doing this is not only closed on the level of the disciplinary communication processes, it is also closed on the level of socialization practices and the attendant recruitment of future practitioners (on the operational closure of modern science see Luhmann, 1990; Stichweh, 1990).

The Modern System of Scientific Disciplines

It is not sufficient to analyze disciplines as individual knowledge producing systems. One has to take into account that the invention of the scientific discipline brings about first a limited number, then many scientific disciplines which interact with one another. Therefore it makes sense to speak of a modern system of scientific disciplines (Parsons, 1977, p. 300ff., Stichweh, 1984) which is one of the truly innovative social structures of the modern world.

First of all, the modern system of scientific disciplines defines an *internal environment* (*milieu interne* in the sense of Claude Bernard) for any scientific activity whatsoever. Whatever goes on in fields such as physics, sociology, or neurophysiology, there exists an internal environment of other scientific disciplines which compete with that discipline, somehow comment on it, and offer ideas, methods, and concepts. There is *normal science* in a Kuhnian sense, always involved with problems to which solutions seem to be at hand in the disciplinary tradition itself; but normal science is always commented upon by a parallel level of interdisciplinary science which arises from the conflicts, provocations and stimulations generated by other disciplines and their intellectual careers.

In this first approximation it is already to be seen that the modern system of scientific disciplines is a very dynamic system in which the dynamism results from the intensification of the interactions between ever more disciplines. Dynamism implies, among other things, ever changing disciplinary boundaries. It is exactly the close coupling of a *cognitively defined discipline* and a *disciplinary community* which motivates this community to try an expansionary strategy in which the discipline attacks and takes over parts of the domain of other disciplines (Westman, 1980, pp. 105–106). This was wholly different in the disciplinary order of early modern Europe, in which a classificatory generation of disciplinary boundaries meant that the attribution of problem domains to disciplines was invariable. If one decided to do some work in another domain, one had to accept that a change over to another discipline would be necessary to do this.

Closely coupled to this internally generated and self-reinforcing dynamics of the modern system of scientific disciplines is the openness of this system to new disciplines. Here again arises a sharp difference to early modern circumstances. In early modern Europe there existed a closed and finite catalogue of scientific disciplines (Hoskin, 1993, p. 274) which was related to a hierarchical order of these disciplines (for example philosophy was a higher form of knowledge than history, and philosophy was in its turn subordinated to faculty studies such as law and theology). In modern society no such limit to the number of disciplines can be valid. New disciplines incessantly arise, some old ones even disappear or become inactive as communication systems. There is no center and no hierarchy to this system of the sciences. Nothing allows us to say that philosophy is more important than natural history or physics more scientific than geology. Of course, there are asymmetries in influence processes between disciplines, but no permanent or stable hierarchy can be derived from this.

The modern system of scientific disciplines is a global system. This makes a relevant difference from the situation of the early nineteenth century, in which the rise of the scientific discipline seemed to go along with a strengthening of national communities of science (Crawford et al., 1993; Stichweh, 1996). This nationalization effect, which may have had to do with a meaningful restriction of communicative space in newly constituted communities, has since proved to be only a temporary phenomenon, and the ongoing dynamics of (sub-) disciplinary differentiation in science seems to be the main reason why national communication contexts are no longer sufficient infrastructures for a rapidly growing number of disciplines and subdisciplines.

The Future of the Scientific Discipline

The preponderance of subdisciplinary differentiation in the late twentieth century is the reason most often cited for the presumed demise of scientific discipline postulated by a number of authors. But one may object to this hypothesis on the ground that a change from disciplinary to subdisciplinary differentiation processes does not at all affect the drivers of internal differentiation in modern science: the relevance of an internal environment as decisive stimulus for scientific variations, the openness of the system to disciplinary innovations, the nonhierarchical structure of the system. Even if one points to an increasing importance of interdisciplinary ventures (and to problem-driven interdisciplinary research) which one should expect as a consequence of the argument on the internal environment of science, this does not change the fact that disciplines and subdisciplines function as the form of consolidating interdisciplinary innovations. And, finally, there are the interrelations with the external environments of science (economic, political, etc.), which in twentieth and twenty-first century society are plural environments based on the principle of functional differentiation. Systems in the external environment of science are dependent on sufficiently stable addresses in science if they want to articulate their needs for inputs from science. This is true for the educational environment of science which has to organize school and higher education curricula in disciplinary or interdisciplinary terms, for role structures as occupational structures in the economic environment of science, and for many other demands for scientific expertise and research knowledge which always must be able to specify the subsystem in science from which the respective expertise may be legitimately expected. These interrelations based on structures of internal differentiation in science which have to be identifiable for outside observers are one of the core

components of modern society which, since the second half of the twentieth century, is often described as *knowledge society*.

Abstract

In the fields of artificial intelligence and cognitive science, computational models of scientific discovery have been implemented in computer programs to support the making of scientific discoveries and investigate the nature of the creative processes of discovery. Over the past four decades, computational models and tools have been created to model many of the diverse theory-oriented tasks, and some experimental tasks, which scientists perform. The models span the full spectrum of scientific disciplines. They have not only given us a deeper insight into the richness of scientific activity and the psychology of creative problem solving, but also have been instrumental in making new scientific discoveries in their own right.

Introduction

Scientific discovery is the process by which novel, empirically valid, general, and rational knowledge about phenomena is created. It is, arguably, the pinnacle of human creative endeavors. Scientific discovery involves a diverse range of activities with which humans strive to search for new scientific knowledge, find explanations for phenomena, revise existing knowledge, or integrate it with new findings. Many academic and popular accounts of great discoveries surround the process with mystery, ascribing them to a combination of serendipity and the special talents of geniuses. However, computational models of scientific discovery have been developed that shed some light on the underlying creative processes. In contrast to more domain specific, applied approaches like data mining or scientific computation, computational models of scientific discovery usually operate on a wider scope. The making of discoveries in particular domains has been frequently used to illustrate the applicability of the models, yet the primary aim of their construction has been to create communicable scientific knowledge and advance human insight and understanding into how discovery processes work in general.

Models as a Scientific Instrument

Models are an important instrument of science, as they provide different ways of making a scientific problem tractable. The design, testing, comparison, and revision of models present a substantial part of scientific day-to-day business. Many scientific models for all kinds of fields, applications, and purposes have been developed to date, each supporting a particular aspect of the scientific process. Most notably, models have a representational function with regard to objects, phenomena, data, and theories. As such, they can be representations of observable behavior, for instance, through the use of idealizations or analogies (e.g., the billiard ball model of gases or the shell model of the atom). With respect to theories, scientific models usually present an interpretation of a calculus, which is based on some formal notation, such as mathematical equations.

Computational Models

One major advantage of computational models over other approaches to the study of scientific discovery lies in the requirements imposed by writing a running computer program. Any ambiguities and inconsistencies in the concepts used to describe discovery processes will become apparent when attempting to coherently encode them in a programing language. Computer programs can perform laborious tasks while maintaining high precision and thoroughness in their performance, such as searching large information spaces, carrying out automated operations on data, and performing inferences according to particular algorithms. Computer programs can also record user inputs or experiment results reliably and in a systematic fashion using computational storage repositories such as files or databases, and make these recordings available as input for further study. Given suitably constrained and well-defined tasks that can be encoded within a common programing paradigm, computers will usually execute these tasks faster than humans. Another advantage of computational modeling is the ability to investigate alternative methods or hypothetical situations. Different versions of a system may be constructed embodying, say, competing representations to investigate the difficulty of making the discovery with the alternatives. The same system can be run with different sets of data, for example, to explore whether a discovery could have been made had there been less data, or had different data been available. Many stages are involved in the development of the models, including, formulation of the problem, engineering of appropriate problem representations, selecting and organizing data, design and redesign of the algorithm, actual invocation of the algorithm, and filtering and interpretation of the findings of the system (Noy et al., 2000). Considering the nature and relative importance of these activities in the development of systems provides further insight into the nature of scientific discovery.

This article contains two main parts. In section Computational Models of Scientific Discovery, an overview of the work on computational models of scientific discovery is presented, covering the evolution of the field from early work to recent developments, the tasks addressed, as well as some comments on the scope and common limitations of the models. The section Computational Models and Tools describes the structure and workings of some representative models and tools that have been developed thus far.

Computational Models of Scientific Discovery

Since the early 1970s, work in artificial intelligence (AI) has developed computational models of scientific reasoning, which

resulted in a range of different discovery systems and tools. Some systems have modeled discoveries from the history of science or simulated the behavior of participants solving scientific problems in the psychology laboratory. Other systems attempt to harness computational power to operate on combinatorial spaces of information in search of new knowledge. Some systems have made significant discoveries in chemistry and biology, such as finding new reaction pathways or genetic networks. The success of these models provides some insights into the nature of human cognitive processes in scientific discovery and addresses some interesting issues about the nature of scientific discovery itself.

General Approaches

Computational models of scientific discovery have been broadly categorized into data-driven and theory-driven approaches (Langley et al., 1987), whereas data-driven and knowledge-driven approaches are distinguished in Valdes-Perez (1999). Many systems present a combination of the above categories, in particular if they address more than one discovery task or try to improve the results of one approach with the help of the other. Data-driven approaches focus on analytical tasks and are often used in domains where scientific knowledge is scarce. A common problem addressed by these approaches is the induction of laws from existing data. The related computational models usually implement some form of heuristic search that aims to find patterns in large spaces of information and data. Knowledge and theory-driven approaches make use of methods that can be informed and controlled by integrating generic and domain-specific knowledge. These approaches aim to synthesize new knowledge, enable reasoning, or inform the construction of explanatory models from theories and existing knowledge.

Scope

Knowledge structures and scientific activities constitute two categories for describing the many components that play a role in the theoretical and experimental processes of science (Shrager and Langley, 1990). Computational models of scientific discovery are often illustrated using a scientific problem from a particular domain to facilitate a single or several scientific activities in an operationalized fashion, such as observation, data elicitation, taxonomy formation, law formation, creation of models, theory formation, explanation, prediction, manipulation of experiments, or the evaluation of results. Depending on the nature of the discovery task addressed, the models integrate a varying range of domain-specific and domain-independent knowledge, information, and data for carrying out the related operations.

Many computational models of scientific discovery that have been developed thus far have exclusively addressed theoretical tasks. While much of the early work focused on taxonomy and law formation (Langley et al., 1987), the range of models available today cover a wider range of activities, including modeling, model revision, and explanation (e.g., Stolle and Bradley, 2007; Bridewell and Langley, 2010; see also Langley, 2000 for earlier examples). However, the modeling of experiments has not been completely neglected as models have been built that design experiments, to a limited extent, by using procedures to specify what properties should be manipulated and measured in an experiment and the range of magnitudes over which the properties should be varied (Kulkarni and Simon, 1988; Cheng, 1992). For these systems, the actual experimental results are either provided by the user of the system or generated by a simulated experiment in the software. Discovery systems have also been directly connected to a robot, which manipulates a simple experimental setup so that data collected from the instruments can be fed to the system directly, eliminating any human intervention (Huang and Zytkow, 1997). Nevertheless, few systems have simulated or supported substantial experimental activities, such as observing or creating new phenomena, designing experiments, inventing new experimental apparatus, developing new experimental paradigms, establishing the reliability of experiments, or turning raw data into evidence. This perhaps reflects a fundamental difference between the theoretical and experimental sides of science. While both clearly involve abstract conceptual entities, experimentation is also grounded in the construction and manipulation of physical apparatus, which involves a mixture of sophisticated perceptual abilities and motor skills. Developing models of discovery that include such capabilities would necessarily require other areas within AI beyond problem solving, such as image processing and robotics.

Limitations

Computational approaches to scientific discovery share many advantages and disadvantages that are characteristic for in vitro research (Dunbar, 1995). In particular, they allow a high degree of control and can be implemented at relatively low cost. However, computational models are also constrained by a bounded rationality that is implicit in their codified structure and function. Many systems perform rather simple, time-constrained tasks that are based on idealized models and usually fail to implement realistically the complex social interactions between scientists in their approach and examination of a scientific problem. Further, particular human characteristics and circumstances that may play an important role in discovery processes are currently difficult to operationalize. Computational models of scientific discovery often abstract from aspects like human creativity, shifts in the focus of attention, motivation, choice and change of problem representation, or irrational reasoning, just to name a few. Computational models usually draw on features of the technical environment in which they exist, such as large data storage capacity, as well as a high precision and thoroughness in their operation. These features render irrelevant some of the human limitations that might otherwise influence the choice of particular discovery strategies and related activities when computational models were absent, and that may play their part in leading to conceptual change and novel discoveries. Examples of these are the iterative recording and revision of results, the handling of anomalies, and activities of abstraction, simplification or analogical reasoning that are used by humans in order to cope cognitively with large amounts of information.

Recent advances in the design of collaborative software systems and the emergence of social academic networks have improved the computational means for social interaction and communication in science. A prominent example is presented by the various projects embedded within the Semantic Web initiative, which facilitate the collaborative construction, inspection, and manipulation of ontologies (e.g., Noy et al., 2000). While computational models of scientific discovery have evolved to address a wide range of scientific activities (Dzeroski et al., 2007), the exact workings of social interaction still escape the level of formalization that would be needed for their comprehensive simulation. This poses the question how else computational models of scientific discovery can successfully integrate social behavior to grow beyond their current limitations. One possible approach might involve embedding human scientific activities within computational discovery systems that are both data and knowledge driven and facilitate a wide range of scientific tasks in a collaborative, rather than fully automated fashion. Some recent work in the biological sciences, for example, has taken steps in this direction, away from pure simulation models toward programmable knowledge platforms that support multiple users (Shrager, 2007).

Tasks

The majority of early discovery systems have modeled a single theoretical task. The predominance of such systems has been taken as the basis for a general criticism of computational scientific discovery. The models were typically poor imitations of the diversity of activities in which human scientists are engaged and, perhaps, it is from this variety that scientific creativity arises. Researchers in this area countered such arguments by claiming that the success of single task systems presents a manifestation of the underlying nature of the process of discovery, that it is composed of subprocesses or tasks that are relatively autonomous. More complex activity can be modeled by assembling systems that perform one task into a larger system, with the inputs to a particular component subsystem being the outputs of other systems. Models that perform multiple tasks demonstrate the plausibility of this claim (e.g., Kulkarni and Simon, 1988; Cheng, 1992; Stolle and Bradley, 2007; and Bridewell and Langley, 2010). The organization of knowledge structures and procedures in those systems exploits the hierarchical decomposition of the overall process into tasks and subtasks. This in turn raises the general question about the number and variety of different tasks that constitute scientific discovery and the nature of their interactions. What distinct search spaces are involved and how is information shared among them? Computational models of scientific discovery provide some insight into this issue. At a general level, many models can be characterized in terms of two spaces, one for potential hypotheses and the other a space of instances or sets of data (Simon and Lea, 1974). Scientific discovery is then viewed as the search of each space mutually constrained by the search of the other. Inferring a hypothesis dictates the form of the data needed to test the hypothesis, while the data will determine whether the hypothesis is correct and suggest in what ways it should be amended (Klahr and Dunbar, 1988; Kulkarni and Simon, 1988). This is an image of scientific discovery that places equal importance on theory and experiment, portraying the overall process as a dynamic interaction between both components. This approach is applicable both to disciplines in which individual scientists do the theorizing and experimenting and to disciplines in which these activities are distributed among different individuals or research groups. The search of the theoretical and experimental spaces can be further decomposed into additional subspaces; for example, Cheng (1992) suggests three subspaces for hypotheses, models, and cases under the theory component, and spaces of experimental classes, setups, and tests under the experimental component.

Representation

Scientists usually create representations like notes and drawings in order to plan their research, reason about problems, and record results. Finding an effective representation may be fundamental to the making of discoveries. This issue has been directly addressed by computational models that contrast the efficacy of different representations for modeling the same historical episode (Cheng, 1996). Consistent with work in cognitive science, diagrammatic representations may in some cases be preferable to informationally equivalent propositional representations (e.g., Cheng and Barone, 2007; Klahr and Dunbar, 1988). Studies from the history of science have shown that particular discoveries were made as a progression through different stages of activities that involved different kinds of representations. An example is presented by Nersessian (2002), who analyzed the accounts of James Clerk Maxwell in an attempt to examine the processes involved in the discovery of electromagnetic theory. Among many interesting insights into his experiments and the role analogical reasoning may have played for facilitating conceptual change, it was also shown that Maxwell employed qualitative, diagrammatic representations for conceptualizing the scientific problem before creating the final quantitative formulation. The different stages of the discovery process and the related tasks and representations have also been the subject of other research in computational scientific discovery (e.g., Langley, 2000) and research on creativity and cognitive science (e.g., Helie and Sun, 2010). Although computational models of scientific discovery argue against any special abilities of great scientists beyond the scope of conventional theories of problem solving, the models also suggest that the ability of some scientists to modify or create new representations may be an explanation, at least in part, of why they were the ones to succeed.

Computational Models and Tools

Many models and tools have been developed since the advent of research on computational scientific discovery. Although the developed systems employ various methods and data structures that are common in Computer Science and Artificial Intelligence AI, their particular implementations and applications overlap, so that a structured overview of the different

types of systems that exist is somewhat difficult to create. Moreover, in contrast to early computational models of scientific discovery, which explicitly focused on exploring cognitive models of discovery processes, many of the later developments seem increasingly applied and domain specific in nature. As a consequence, even though some of these tools may make valuable contributions to our understanding of discovery processes, it is sometimes unclear whether they have been developed to represent models of discovery in their own right, or whether they use and extend models of discovery more implicitly to focus on practically addressing a scientific problem in a particular domain. The tools described below present but a small selection of examples from each of the previous decades to illustrate somewhat the breadth of applications for which models have been developed and show how systems have evolved to implement an increasing number of tasks.

Discovering Laws from Data – BACON (1978)

Many computational models of discovery can be conceptualized as performing a recursive search of a space of possible states, or expressions, defined by the representation of the problem. Procedures are used to search the space of legal states by manipulating the expressions and using tests of when the goals or subgoals have been met. To manage the search, which is typically subject to potential combinatorial explosion, heuristics are used to guide the selection of appropriate operators. This is essentially an application of the theory of human problem solving as heuristic search within a symbol processing system (Newell and Simon, 1972). BACON (Langley et al., 1987) finds algebraic formulas as parsimonious descriptions of quantitative data. States in the problem search space of BACON include simple algebraic formulas; such as P/D or P^2/D, where, for instance, P is the period of revolution of planets around the sun and D is their distance from the sun. Tests in BACON attempt to find how closely potential expressions match the given quantitative data. Given quantitative data for the planets of the solar system, one step in BACON's discovery path finds that neither P^2/D nor P/D is constant and that the first expression is monotonically increasing with respect to the second. Given this relation between the expressions, BACON applies its 'increasing' operator to give the product of the terms, that is P^3/D^2. This time, the test of whether the expression is constant, within a given margin of error, is true. $P^3/D^2 =$ constant is one of Kepler's planetary motion laws. For more complex cases with larger numbers of variables, BACON uses discovery heuristics based on notions of symmetry and the conservation of higher order terms to pare down the search space. The heuristics use the underlying regularities within the domain to obviate the need to explore parts of the search space that are structurally similar to previously explored states. Following such an approach, computational models have been developed to perform tasks spanning a full spectrum of theoretical activities including the formation of taxonomies, discovering qualitative and quantitative laws, creation of structural models and the development of process models (Langley et al., 1987; Shrager and Langley, 1990; Cheng, 1992). The range of scientific domains covered is also impressive, ranging from physics and astronomy, to chemistry and metallurgy, to biology, medicine, and genetics.

Simulating Historical Discoveries – KEKADA (1988)

KEKADA (Kulkarni and Simon, 1988) is a system that uses heuristics for discovering chemical pathways, based on a two-space model of problem solving and learning similar to that used in BACON (Newell and Simon, 1972; Simon and Lea, 1974). The system simulates the discovery of the urea synthesis cycle, which was made by the biochemists Hans Adolf Krebs and Kurt Henseleit in 1932. KEKADA searches both a space of rules, which contains hypotheses about the problem, and a space of instances, which represents possible experiments that can be carried out for testing the hypotheses. The search is configured by heuristics that are based on the particular expectations associated with the outcome of experiments, and a measure of confidence with respect to the rules applied. The system operates in a cyclic fashion in that experiments are chosen from the instance space, whose outcome changes the state of both spaces, after which another experiment is selected, and so on. KEKADA identifies any experimental results that do not comply with previous expectations as anomalies, and will attempt to find an explanation for such results. Although the simulation carried out by KEKADA was considered largely identical to the original account of the discovery, its success has also been questioned, for example, because the heuristics encoded in the system may have contained knowledge that was not available to Krebs and his colleagues at the time. Nevertheless, KEKADA presented one of the first computational systems to address multiple discovery tasks, including hypothesis formation and experimentation.

Using Literature as Data for New Discoveries – ARROWSMITH (1990)

ARROWSMITH (Swanson, 1990) is a data-driven discovery tool that searches medical literature for intersecting information based on the joint use of keywords or mutual citations. In general, the system attempts to find connections between diseases, their causes and possible treatments and recombines any factual knowledge found in the documents to infer new knowledge. For example, the system has been shown to combine the facts that (1) magnesium may inhibit spreading depression in the cortex and (2) migraine attacks may be a symptom of depression, to infer that magnesium could act as a relief for migraine. With respect to this example, clinical trials have subsequently found supporting evidence that a deficiency of magnesium may indeed be the cause for migraine.

ARROWSMITH uses some linguistic heuristics to streamline connections found and proposes suitable indexing of documents to improve search and prevent a combinatorial explosion of relations found. The system is still being used in the medical research community and has been extended further to improve search results. For example, Torvik and Smalheiser (2007) describe the development of a quantitative regression model that uses additional criteria

to establish and rank the probable relevance of any connections found by the tool.

Finding New Chemical Reaction Pathways – MECHEM (1992)

MECHEM (Valdes-Perez, 1992) is a theory-driven system for discovering chemical reaction pathways. Given empirical data on initial materials and knowledge about the products of chemical reactions, the system will infer possible reaction pathways for these materials, that is sequences of individual chemical reactions that explain how the reaction products come about. MECHEM applies heuristics that are based on existing knowledge about chemical reactions in order to constrain the number, plausibility, and likelihood of possible reaction pathways. For example, the system will favor those results that feature the fewest number of steps. However, the hypotheses are "not drawn from any stored catalog of common reactions; rather, they are generated from basic principles using algorithms minimally slanted toward particular solutions" (Valdes-Perez, 1999). In the context of modeling historical discoveries, this suggests that the knowledge base used by MECHEM can be adjusted at a relatively fine granularity to represent more realistically the bodies of knowledge that were available to scientists at some point in time.

Modeling Dynamic Systems – LAGRAMGE (1997), PRET (2007), SC-IPM (2010)

Since the emergence of BACON (Langley et al., 1987), a number of equation discovery systems have been developed that attempt to find mathematical models of data. In contrast to earlier systems, more recent developments increasingly use existing domain knowledge to improve the results of their inference mechanisms. LAGRAMGE (Todorovski and Dzeroski, 1997) is an example of an earlier system that has targeted dynamic systems and is able to specify models using algebraic as well as differential equations, using context-free grammars to define its search space. SC-IPM (Bridewell and Langley, 2010) is based on this approach and presents a system for inducing quantitative process models from time-series data. Given a specification of entities, processes, and observations that describe a system's dynamics, the program will generate explanations and predictions over this data. SC-IPM uses regression methods to operate on the data and domain knowledge to constrain its heuristic search for plausible models.

PRET (Stolle and Bradley, 2007) is a tool for automatic system identification that constructs models for given dynamic systems in the form of ordinary differential equations. Although originally designed for engineering tasks, the system employs a variety of AI methods to generate and test candidate models, including qualitative reasoning, geometric reasoning, backward chaining, numerical simulation, and others. PRET takes as input observations about the behavior of a given system, and can also take into account user-defined hypotheses and task-specific constraints. Based on its internal methods, PRET can make inferences about potential models on multiple abstraction levels, in that it applies those methods first that involve the lowest computational cost. For example, the system will attempt to rule out a potential model using qualitative reasoning first, before initiating a (computationally expensive) quantitative parameter estimation. Eventually, PRET will create a formal mathematical model of the dynamics of the system.

Equation discovery systems have been successfully applied to a range of theoretical and real-world problems in domains such as physics, robotics, biology, or climatology. Despite their representational limitations with respect to noncontinuous aspects of processes, these models will perform important functions in future discovery systems.

Conclusions and Future Directions

Given the extent of development work necessary to build a discovery system, it seems appropriate to attribute discoveries as much to the developer as to the system itself, although without the system many of the novel discoveries would not have been possible. This does not imply that machine discovery is impossible, but that care must be taken in delimiting the capabilities of discovery systems. The ability of systems like KEKADA (Kulkarni and Simon, 1988) to change their goals to investigate any surprising phenomenon they discover suggests that systems can be developed that would filter and interpret the output of existing systems, by constraining the search of the space defined by the outputs of those systems using metrics based on notions of novelty. Developing such a system, or other systems that find problems or that select appropriate representations, will require the system to possess substantially more extensive knowledge of the target domain. Although there have been vast advances in automated approaches such as inductive process modeling (Bridewell and Langley, 2010) and system identification (Stolle and Bradley, 2007), comprehensive knowledge-based systems are costly and time consuming to build. It therefore appears that the future of discovery systems may be in collaborative support systems for domain scientists rather than fully autonomous systems (Valdes-Perez, 1999; Shrager, 2007; Grau, 2009). These systems use multiple tools and representations to exploit the respective strengths of human scientists and the computational power of the models to compensate for each other's limitations.

Emerging fields such as Computational Biology or Astroinformatics have led to the development of domain-specific tools that implicitly build on computational models of scientific discovery, yet focus mostly on formalisms developed by Computer Science, rather than AI to make discoveries and solve scientific problems. While the handling of massive amounts of data is considered an important task in these domains, it has also been suggested that (1) increasing effort should be made to integrate more of the existing knowledge about models of discovery to improve these approaches, (2) the creation of models that generalize over a particular domain or scientific problem should not be neglected in order to re-enforce the creation of knowledge that can be communicated across disciplines, and (3) research activities concerning scientific computation should be balanced with those that examine the nature of discovery processes, in order to prevent the creation of a research bias

toward data-rich domains, and to continue work on equally important scientific problems where less data are available (Dzeroski et al., 2007).

Computational models of scientific discovery have evolved to handle multiple tasks and can support discovery systems that attempt to address increasingly complex problem domains. Some of the most recent research in AI, Discovery Informatics, and Cognitive Science addresses important topics such as the exploration of ill-structured knowledge domains, the modeling of structural and temporal aspects of processes, the development of multiscale models, or the integration and representation of heterogeneous knowledge (e.g., Grau, 2009). However, further effort is also needed to develop computational models for the support of experimentation, such as systems that design experimental setups or invent new apparatus for carrying out experiments.

Scientific Evidence: Legal Aspects

Joseph Sanders, University of Houston Law Center, Houston, TX, USA

Abstract

Legal consumption of scientific evidence has grown rapidly in the last few decades. Legislatures, administrative agencies, and courts turn to science to provide factual justification for laws, regulations, and decisions. The law–science relationship is characterized by tensions resulting from both cultural differences and the questions law puts to science. All legal systems control the way in which science is introduced into the legal process, but the way in which control is exercised is shaped by whether the legal system is adversarial or inquisitorial. In the process, law helps to define 'science' and the scientific enterprise. In the modern state, law and science have grown increasingly interdependent. By invoking science, law is able to justify difficult policy decisions. In turn, legal decisions contain an implicit scientific epistemology, which helps to maintain science's dominant position in Western society.

Introduction

Expertise, scientific and otherwise, has been part of the legal landscape for centuries (Hand, 1901; Landsman, 1995). In the last century, the role of scientific evidence in the law has expanded rapidly both in regulatory settings and in litigation. Statutes and treaties routinely require agencies to provide scientific justifications for regulatory decisions within and among nations (Peel, 2010). National and international policy disputes are increasingly fought out within the discourse of science (Cranor, 2006). Courts are another large consumer of science. In both criminal and civil cases, parties believe scientific testimony will make their case stronger. As science's role has grown, so has interest in the relationship between law and science. This article reviews the nature of the science–law relationship.

What Law Wants from Science

In both the administrative and the courtroom contexts, law is most frequently interested in acquiring scientific answers to practical questions of causation (e.g., which cancers are caused by exposure to benzene or other toxic agents, how greenhouse gases affect climate change, and how agricultural subsidies affect fair trade) and measurement (e.g., what is the alcohol level in a driver's blood and what are the emission levels at a power plant). These questions lead to a second set of questions about whether specific fields and techniques (e.g., epidemiology, a breathalyzer, and market surveys) are capable of producing reliable results. Theoretical questions per se, are generally of secondary interest, useful insofar as they help courts and regulators to choose among conflicting measurements, extrapolations, or causal assertions.

Tensions in the Law–Science Relationship

The law–science relationship is made more difficult by a number of inherent tensions (Haack, 2009). The tensions arise from two different sources: difference in scientific and legal cultures and differences in the causal questions they typically address.

Culture

The core objectives of legal systems are different from those of science. The business of science is open-ended inquiry while the business of law is to enshrine policy in rules and then to use those rules to resolve disputes.

The nature of open-ended scientific inquiry is reflected in Robert Merton's four norms of scientific inquiry: universalism, organized skepticism, communism, and disinterestedness (Merton, 1973). Two norms – communism (the collective ownership of data and knowledge), and disinterestedness (lack of desire to arrive at any particular outcome in searching for the truth) – are particularly relevant here. One does not have to believe that these norms – perhaps better described as epistemological ideals – are always followed in scientific inquiry to appreciate that they may be more or less valued in different legal settings. The scientific arena, like the legal arena, is often contested ground and complete individual disinterestedness is rare in either context. However, because legal actors do not see inquiry as their primary business, they do not share with those inculcated in scientific values a set of professional ethics supporting this epistemological posture.

It is common to divide modern legal systems into two types: inquisitorial and adversarial (Langbein, 1985; Van Kampen, 1998; Sklansky, 2009). Because all legal systems contain both adversarial and inquisitorial components, it is best to think of these as ideal types (Weber, 1949: p. 90).

Adversarial systems are especially likely to encourage a set of normative beliefs that promote party control and client advocacy over other values. The morality of adversarial legal systems is a matter of considerable debate (Luban, 2007; Markovits, 2008; Wendel, 2010). What is not debatable, however, is that adversarial systems do not view unbiased inquiry embodied in the norms of communism and disinterestedness as a cardinal legal virtue.

The impact of legal systems is not solely a matter of normative values. Much turns on how these values shape the structures and procedures legal systems put in place to affect the way law receives scientific information. Here, it is unwise to view any legal system as a single, homogenous regime. One should distinguish the use of scientific expertise in the administrative context from the use of science in the adjudication of disputes. Administrative agencies in both inquisitorial and adversarial legal systems routinely employ experts presumed to be capable of monitoring and assessing the science presented by interested parties and agencies may enjoy the luxury of postponing decisions when reliable evidence is unavailable. As such, administrative procedures come closer to approximating the organization of scientific inquiry.

Even here, however, one observes differences across legal cultures. Jasanoff (1991) contrasts the relatively closed, consensual, and nonlitigious British regulatory approach with the open, adversarial, and adjudicatory style found in the United States.

Fewer ameliorative structures are available in the context of litigation than in the administrative realm. Absent the use of their own court-appointed experts, decision makers have limited resources with which to assess the merits of expert arguments. Much, therefore, turns on how experts are chosen and how their knowledge is brought into the dispute. In inquisitorial legal systems, e.g., Belgium, Egypt, France, Germany, and Japan, experts are chosen by the judge trying the case. The judge also controls the expert's input (Jurs, 2012; Shaham, 2010). Parties may be given the opportunity to object to a particular expert, question the expert about the opinion rendered, or hire their own expert to rebut the court-appointed expert; but it is very difficult to successfully challenge the admissibility or even the correctness of an expert's report (Langbein, 1985; Jones, 1994).

The adversarial legal system that exists in the United States eschews these and other structural devices in favor of a set of arrangements Oscar Chase (2005) terms American procedural exceptionalism. Among other things, the set of structures in the American system permits the parties to choose, pay, and present experts and their testimony to the fact finder, which often is a civil or criminal jury. These arrangements produce selection biases (experts outside the mainstream of the opinion of their field are chosen because they are more willing than their colleagues to provide an opinion based on less evidence), and often produce witness bias insofar as party experts, when offering their opinion, eschew nuances that they might otherwise have expressed (Sanders, 2007). Moreover, party examination and cross-examination of witnesses frequently creates the perception that there is far less agreement on scientific questions than in fact exists (Angell, 1996; Haack, 2009).

Legal systems may try to ameliorate the effects of these structures in various ways, e.g., by establishing admissibility criteria (discussed below), but these devices are not a full substitute for changing the structures themselves in significant ways (Bernstein, 2008). The reluctance of legal systems to change these structures speaks to the fact that differences in legal cultures are related to larger cross-cultural differences. For example, open, adversarial approaches reflect a coordinate organization – to be distinguished from a more hierarchical organization – of justice (Damaska, 1986), which in turn is more pronounced in societies that are more individualistic and lower on measures of power distance (Hofstede, 1980; Kagan, 2001).

Scientific vs Legal Inquiry

Cultural differences are not the only source of tension in the law–science relationship. Two additional, and perhaps more intractable, sources relate to the nature of inquiry in scientific vs legal culture, specifically differences related to *timing* and differences between the *types of causal questions* normally addressed by science and the causal questions often at stake in legal proceedings. Again these differences play out differently in administrative rule making and courtroom settings.

A key component of much scientific inquiry is its long-term view, its lack of concern with immediate results. However, when law uses science, time is almost always relevant. In administrative settings, a policy must be set; and in litigation, a dispute must be settled. This produces pressures to ask experts to offer their 'best guess' and to draw a conclusion with less warrant than would be called for if one could simply wait for more evidence.

The lack of fully developed scientific knowledge is not of equal significance in the administrative and litigation arenas, because they do not require the same level of proof before reaching a conclusion. In administrative settings, it may be sufficient to know, for example, that a substance poses a significant potential risk. In a courtroom, in order to prevail, the plaintiff often will be held to a higher burden of persuasion. Scientific evidence that is sufficient in the regulatory context may be considered insufficient in court. For example, animal studies showing a relationship between saccharin consumption and cancer may be sufficient to cause an agency to impose regulations on human exposure to the sweetener, but would be insufficient to permit a plaintiff to prevail on a claim that saccharin at normal dose levels causes cancer in humans. Therefore, in litigation the question frequently arises as to whether there is some minimal warrant below which an expert should be prohibited from offering any opinion. One may even ask whether there are whole areas of alleged expertise, such as forensic bite-mark evidence and handwriting analysis, currently routinely admitted into evidence, that should be excluded absent better support for the claims of experts who testify in these areas (Risinger et al., 1989; Beecher-Monas, 2009; National Research Council, 2009: Chapter 5).

The type of causal question addressed in legal settings presents still another difficulty for the law–science enterprise. As numerous scholars have noted, science tends to focus on the general law rather than on the particular case. As a result, science usually seeks to uncover the effects of causes. Law, too, is frequently interested in such questions. What are the effects of exposure to asbestos? What are the chemical attributes of substances that cause human injury? What threshold should be established for daily exposure to benzene? At trial, however, courts often require testimony about the particular case. When this is the case, courts are interested not in the effects of causes, but rather in the causes of effects (Dawid, 2011).

Some causes-of-effects questions can be answered with a significant degree of certainty, e.g., the probability that DNA

left at a crime scene matches a defendant's DNA. But most questions of this type cannot be answered with anything like this degree of certainty (Faigman, 2010). Scientists may be able to state whether benzene causes various types of leukemia, but they have far less to say about whether a particular plaintiff's leukemia was caused by benzene. This problem is particularly acute with respect to many types of forensic evidence in criminal cases where there is little or no reliable empirical work underlying the opinions of forensic experts (Cole, 2001; National Research Council, 2009). Once again, in the face of this difficulty, courts typically lower the threshold of justification required for an expert to testify (Sanders, 2010).

Legal Control of Scientific Evidence

The way in which legal systems control expert inputs reflects both the legal culture and the law's view of science. In litigation, the fundamental distinction remains between systems in which judges pick experts, and those in which the parties do so. Judges have networks they can turn to in choosing an expert. In some jurisdictions, they are assisted in this task through formal registries of qualified individuals. This is the case, for example, in France, Germany, and Japan (Jurs, 2012; Taylor, 1996).

Judicial appointment of experts through a set of registries makes several assumptions about the nature of science and the proper relationship between law and science. A system that permits the parties to select experts with unfettered discretion rests on a very different set of assumptions. The history of admissibility decisions in US courts provides a useful way to explore these assumptions.

Control of scientific testimony at trial is much more difficult when parties are permitted to select experts. Precisely, because the knowledge possessed by the scientist is beyond the ken of the court, the judge (or the jury) often is not in a good position to determine whether what the expert is offering is or is not helpful. In a 1923 decision, *Frye v. the United States*, a federal court offered one solution to this problem: defer to the judgment of the community of specialists who are the guardians of each area of knowledge. Under the *Frye* rule, experts may testify only if the subject of their testimony is sufficiently established to have reached 'general acceptance' in the relevant scientific community. However, the *Frye* test was applied almost exclusively to criminal cases and even there the test was applied only to novel expert evidence that had not previously passed muster. This laissez-faire attitude prevailed until relatively recently. The most noteworthy example of change is in the United States, although a similar trend has occurred in Canada (Vidmar, 1999). In the 1980s, judicial control of scientific expert testimony at trial became a high-profile issue in the United States with the rise of the asbestos litigation and other mass torts, i.e., torts involving thousands of plaintiffs, which in turn increased the concern that experts chosen by the parties produce less reliable testimony (*see* Expert Testimony).

In 1993, in *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, and subsequent opinions, the US Supreme Court moved the federal courts away from the *Frye* rule, a move followed by most state jurisdictions as well. In its place, courts have moved toward directly examining the structure of the expert's argument and the empirical evidence available to support the various steps in the argument. When the 'analytical gap' between the evidence and the argument becomes too great, the expert testimony is excluded (*General Electric Co. v. Joiner*, 1997; Faigman et al., 2013: Chapter 1).

Legal Understanding of the Scientific Enterprise

Liberal admissibility rules reflect an adversarial legal system that institutionalizes mistrust of all claims to superior authority. They are consistent with the values of a low-power distance culture, i.e., a culture that affords relatively less legitimacy to elite authoritative opinion and, therefore, is skeptical that scientists are entitled to a privileged status. They are also consistent with the view that science is strongly influenced by other forces in society. These are perspectives on the scientific enterprise that are associated with those who adopt social constructionist views of science, i.e., a view that the social organization of science plays a large role in the production and shape of 'scientific knowledge' (Haack, 2003; Zammito, 2004).

The new admissibility filters in the United States and elsewhere clearly reject a social constructionist test, if by this one means the belief that scientific conclusions are solely or largely the result of social processes within the scientific community. At their core, these approaches require of judges that they become sufficiently knowledgeable about scientific methods so that they can fairly assess the validity of evidence offered at trial. This requirement that scientific testimony must pass methodological muster reflects an objectivist view of science.

This does not mean that the legal system necessarily has a utopian vision of science. Factors that courts consider in assessing admissibility include whether the theory or technique underlying the expert's testimony is falsifiable and has been tested, the error rate of any techniques employed, whether the expert's research was developed independent of litigation, whether the testifying expert exercised the same level of intellectual rigor that is routinely practiced by experts in the relevant field, whether the subject matter of the testimony had been subjected to peer review and publication in refereed journals, and, in a partial retention of the *Frye* test, whether the theory or technique had achieved general acceptance in the relevant scientific community. A number of these factors reflect the skeptical view that scientists frequently fail to live up to Merton's norms and that they are strongly influenced by other considerations that are both internal and external to their work (Caudill and LaRue, 2006). Even after *Daubert*, the legal system views expertise with considerable skepticism.

In their use of scientific evidence, both courts and administrative agencies seem to distinguish the process of science from its products. They accept the insight that the process of doing science is a social enterprise and is subject to the buffeting, often distorting winds of social, political, economic, and legal influences. Nevertheless, courts, agencies, and legislatures assume that the products of science may state a truth or an approximate truth about the world. The legal system's view of science adopts a version of what Cole (1992) calls a realist–constructivist position, i.e., science is socially constructed both in the laboratory and in the wider community, but the construction is constrained by input from the empirical world.

The focus on testing of hypotheses is a search for some assurance that the expert has given the empirical world a reasonable opportunity to influence and constrain the expert's conclusions. Ultimately, a prevailing legal view of science holds that there are a set of (social) practices – often given the shorthand name 'the scientific method' –that increase the likelihood someone will make positive contributions to knowledge; a set of practices that scientists themselves frequently point to as the sources of past scientific success (Goldman, 1999). It is worth noting that in the most recent US Supreme Court pronouncement in this area, *Kumho Tire Co. v. Carmichael* (1999) declares that *Daubert* applies to all expert testimony. Admissibility turns on 'reliability,' not on whether something is or is not 'scientific' (Haack, 2010).

There is a large dose of pragmatism in all of this, of course, and admissibility rules have been cited as an example of "the common law's genius for muddling through on the basis of experience rather than logic" (Jasanoff, 1995: p. 63). Not surprisingly, some have criticized the courts for failing to adopt a philosophically coherent admissibility rule. The court's admissibility rulings and the administrative agency use of science to assist policy making do seem to have proceeded in happy obliviousness to the 'science wars' that raged for the last half of the twentieth century between the defenders of a more traditional, positivist view of science and those critics who emphasize its historical, political, social, and rhetorical aspects (Fleck, 1979/1935; Kuhn, 1962; Leplin, 1997; Latour, 1999). However, like many wars, science wars seem to rumble along without a final resolution of the issues that gave rise to the conflict in the first instance (Labinger and Collins, 2001; Haack, 2003). In light of this standoff, legal pragmatism is, perhaps, the wisest course.

The rejection of fully relativist or fully idealist views of science does not mean all legal actors hold identical views. It would be valuable to map the beliefs of legal actors on central disputes in the science wars and how these beliefs impact their use of science. For example, if, as seems likely, plaintiff personal injury lawyers in the United States hold a more relativist view of science than do their defense counterparts, how does this affect their selection and preparation of experts and, in turn, how are these experts received in courts?

Law–Science Interdependence

Law's approach to science should not be understood in terms of the law's beliefs about science alone but rather in terms of the law–science interaction. There are several dimensions to this relationship. First, although modern legal systems may recognize that scientists are influenced by the social world around them, a modern legal system that would permit radical deconstruction which in turn would undermine science's claim to special status is difficult to imagine (Fuchs and Ward, 1994). The modern state is increasingly dependent on science as a source of legitimacy. By turning to science for solutions to complex environmental and safety issues, legislatures are able to avoid making difficult political choices while giving the appearance of placing decision making in the hands of apparently neutral experts who are held in very high esteem relative to other elites (Lawler, 1996). The advantages of this approach are so great that agencies at times engage in a 'science charade' in which they wrap their decision in the language of science even when there is very little research supporting a regulation (Wagner and Steinzor, 2006).

Second, and related to the first observation, the law–science interaction is one of the important ways in which the state helps to produce and maintain the dominant position of science in Western society. In both its administrative and judicial actions, law defines what is and what is not scientific knowledge, and thereby sometimes assists and sometimes impedes science in the important boundary maintenance work of excluding many from the community of 'scientists.' Until quite recently, for example, law single handedly helped many areas of forensic science to maintain the mantle of 'science' in the face of substantial evidence that many claims had little empirical support (Mnookin et al., 2011).

Even when they admit weakly supported testimony, however, legal decisions maintain an implicit epistemology that reinforces a realist view of scientific knowledge. When courts and other institutions of the state reject a relativist view of science that argues the empirical world has little, if any, influence on what is accepted as true by the scientific community, they help to marginalize anyone who adopts this position. There can be little doubt that the view is given little or no attention in law.

Third, as discussed above, the contours of the law–science interaction are shaped by the values underlying a society's legal system. One may hypothesize that all legal systems lean toward an epistemology of science and the scientific enterprise that fits comfortably within their dominant methods of law making and dispute settlement. One might expect, therefore, that legal actors in inquisitorial systems would be even more skeptical of a constructivist view of the scientific enterprise than those in adversarial legal systems.

Effects of Growing Interdependence

As this article attests, science's impact on legal processes grows apace. In many areas, an attorney unarmed with scientific expertise operates at a significant disadvantage. However, a growing number of treatises attempt to inform lawyers and judges of the state of scientific knowledge in various areas (Faigman et al., 2013). At the level of the case, there is some evidence that scientific concerns are altering the way courts and other legal actors address some types of supposed expertise (National Research Council, 2009).

What is the effect of law on science? If the supply of science on some issues is affected by demand, legal controversy should draw scientists to research topics they might otherwise have eschewed. There is evidence that this does occur. The subject matter of scientific research is shaped by legal controversy in a wide number of areas (Schuck, 1986; Sobol, 1991). Some have argued that law's interest has an additional effect of causing the production of 'worse' science (Huber, 1991), but it might also be argued that in areas such as DNA testing, law's interest has produced better science and better technology than might otherwise have existed.

Scientific groups often attempt to surround themselves with a social structure that keeps society at a distance. Increasingly,

they also attempt to propagate ethical standards for those who offer expert testimony in courts, reflecting the widespread belief that scientists who typically appear in legal arenas frequently disregard accepted interpretative canons. Finally, legal use of science affects the closure of scientific debates (Sanders, 1998). On the one hand, law may perpetuate controversy by supplying resources to both sides. On the other hand, it may help to bring a dispute to closure by authoritatively declaring one side to be correct.

Abstract

There are three main approaches to scientific explanation in the philosophical literature. The unification approach claims that science explains by fitting the particular facts and events within a general theoretical framework. The mechanistic approach claims that science explains by identifying mechanisms. According to the manipulationist approach an explanation ought to be such that it can be used to answer a "what-if-things-had-been-different question." The article examines whether these three approaches are compatible or not in the case of the social sciences, and it concludes by defending explanatory pluralism.

Introduction

The three philosophical approaches to scientific explanation that are currently dominating the discussion are the unification approach, the causal/mechanistic approach, and the manipulationist approach. The unification approach claims that science explains by fitting the particular facts and events within a general theoretical framework. The mechanistic approach claims that science explains by identifying mechanisms understood as entities and activities organized such that they are productive of regular changes from start to termination conditions. Finally, the manipulationist approach claims that explanatory activity consists mainly in answering the "what-if-things-had-been-different question." I will address the issue of compatibility of these three approaches with a specific focus on the social sciences. Are those philosophical accounts of explanation compatible with each other and if yes, in what sense and how exactly?

The Three Main Current Philosophical Theories of Explanation

The philosophical discussion on the theory of scientific explanation centered for many decades around the epoch-making essay of Carl C Hempel and Paul Oppenheim, 'Studies in the Logic of Explanation.' Even when philosophers developed alternative views, the Hempel and Oppenheim (1948) paper served as the default position. At the end of many decades of debate three powerful schools of thought seem to dominate the scheme today: the unification approach, the mechanistic approach, and the manipulationist approach.

The unification thesis, whose chief proponents are Friedman (1974) and Kitcher (1981, 1989), holds that scientific understanding increases as one decreases the number of independent assumptions that are required to explain what goes on in the world. It seeks laws and principles of high generality with the aim of constructing a coherent world picture and fitting particular facts within this framework. Besides, it is not committed to the world picture being deterministic since it is perfectly compatible with the position that basic laws can be irreducibly statistic. The thrust of the central argument of this approach is nicely summarized in the following quote from the classic paper of Friedman (1974, 15): "I claim that this is the crucial property of scientific theories we are looking for; this is the essence of scientific explanation – science increases our understanding of the world by reducing the total number of independent phenomena that we have to accept as ultimate or given. A world with fewer independent phenomena is, other things equal, more comprehensible than with more." The unification approach being, of course, different from the received view of Hempel–Oppenheim, it still remains somehow close to it (mainly in virtue of its insistence on deductivism).

Some new and important work on the unification approach that stresses different dimensions of unification has been produced (for a review Psillos, 2002), and it is characteristic for its relevance that any new theoretical endeavor on scientific explanation feels obliged to take a position vis-à-vis this approach. For the purposes of this paper it will be Kitcher's formulation that will be preferred, which focuses on the scarcity of patterns of derivation. Unification is reached by deriving descriptions of many types of phenomena using one or a few argument patterns over and over again respecting certain constraints, stringency being the most important one.

The causal/mechanical approach to scientific explanation was born mainly as an attempt to repair the two most serious problems of the received view, i.e., the problem of causal asymmetries (associated with the famous flagpole counterexample) and the problem of relevance (associated with the famous example of the hexed table salt). Besides Railton (1978, 1981) and Humphreys (1981, 1989), it is Wesley Salmon who has most prominently argued in favor of bringing 'cause' back into 'because.' The straightforward way to remedy the main problems of the Hempel–Oppenheim model is supposed to consist in integrating a theory of causality into the theory of explanation or, in other words, in providing scientific explanations by identifying causes of events and/or processes. Since this approach tries to take account of the explanatory practices in science (mainly physics), it aims not only at derivations of low-level laws and generalizations from higher level theories but also at elucidating the mechanisms at work. To explain is, thus, to expose the internal workings, to lay bare the hidden mechanisms, to open the black boxes that nature presents to us. This view makes explanatory knowledge into knowledge of the hidden mechanisms by which nature works. Salmon (1984) has tried to specify the notion of mechanism by pointing to causal processes: According to his

 http://dx.doi.org/10.1016/B978-0-08-097086-8.63100-8

theory those processes (and only those) are causal that are capable of transmitting a mark.

The first decade of the new millennium has seen an explosion of work in this direction. On the one hand, the seminal paper of Machamer et al. (2000) has provoked further the 'thinking about mechanisms.' On the other hand, further work on causality has been produced, and the accounts of causality have reached a higher level of technical sophistication than any of the accounts in the past (Cartwright, 2007). Mechanisms as "entities and activities organized such that they are productive of regular changes from start or set-up to finish or termination conditions" (Machamer et al., 2000, p. 3) should be sought in order to be able to explain how a phenomenon comes about or how some significant process works – this is the main message of the mechanistic approach to explanation. The search for mechanisms goes hand in hand with three claims: (1) explanations should provide causes (or reasons); (2) explanations should make phenomena intelligible; (3) explanations should exhibit the continuity among the explaining parts (Machamer, 2009). Salmon's causal/mechanical approach was mainly inspired by physics, and his mark-transmission (and later in Salmon (1998) the conserved quantity-transmission) theory of causal processes was tailored to physics, whereas the modified mechanistic approach has extended its reach to the life sciences, the cognitive sciences, and the social sciences. Defenders of this approach in the life sciences claim that mechanistic explanations differ from more traditional, nomological explanations because (1) they are not limited to linguistic representations and logical inference, but employ frequently diagrams to characterize mechanisms and simulations to reason about them; (2) the fact that mechanisms involve organized systems of component parts and operations provides direction to both the discovery and testing of mechanistic explanations; and (3) models of mechanisms are developed for specific exemplars and are not represented in terms of universally quantified statements (Bechtel and Abrahamsen, 2005; Bechtel, 2006; Darden, 2006; Bogen and Machamer, 2011).

In the cognitive neurosciences, the mechanistic approach points to the fact that explanations in neuroscience describing mechanisms are multilevel and integrate multiple fields (Craver, 2007; Bechtel, 2008). Finally, in the social sciences, though the problem of interpretation of meaningful actions remains important (Mantzavinos, 2005, 2012), a great number of both philosophers and practicing scientists hold the view that social scientific explanations require the discovery of the underlying causal mechanisms that give rise to the outcomes of interest (Hedström and Swedberg, 1996; Demeulenaere, 2011). The search for causal mechanisms is often combined with the position of methodological individualism (Mantzavinos, 2009), but more recently also with the position of methodological localism (Knight, 2009; Little, 2009). All in all, judging from the recent wealth of publications on the mechanistic approach and how it can be applied on many different domains of science, one would apparently not be very wrong to state that this approach is in the process of becoming the new mainstream in the theory of explanation.

The manipulationist approach of Jim Woodward is the third philosophical account of explanation that has gained prominence in recent years. This approach was designed as an alternative to the common view that explanation involves subsumption under laws. According to Woodward (2000, 2003) whether or not a generalization can be used to explain has to do with whether it is invariant rather than with whether it is lawful. A generalization is invariant if it is stable or robust in the sense that it would continue to hold under a relevant class of changes. For example, a generalization can be invariant even if it has exceptions or holds only over a limited spatiotemporal interval. A relationship among some variables (or magnitudes) X and Y is said to be causal if, were one to intervene to change the value of X appropriately, the relationship between X and Y would not change and the value of Y would change. In a nutshell, an explanation for Woodward ought to be such that it can be used to answer what he calls a "what-if-things-had-been-different question," i.e., the explanation must enable us to see what sort of difference it would have made for the explanandum if the factors cited in the explanans had been different in various possible ways.

Summarizing, it seems that there are three viable accounts in the philosophical theory of explanation: the unification approach, the mechanistic approach, and the manipulationist approach. The question is whether some or all of them are compatible, and if yes, in which sense. The fundamental issue this article is tackling is whether one can build bridges between the different theories of explanation.

The Question of the Compatibility of the Three Philosophical Theories of Explanation

The main question, thus, is whether the unification approach, the mechanistic approach, and the manipulationist approach to explanation are compatible, and, if yes, how exactly. Kitcher (1985) has christened the unification approach as a 'top-down' approach since scientific explanations are supposed to generally unify the understanding of the world by fitting the particular facts and events within a general theoretical framework – explanations serve to systematize knowledge in the most efficient way. The mechanistic approach is, on the contrary, according to Kitcher's (1985) terminology, a 'bottom-up' approach, since it aims at identifying mechanisms and provides explanatory knowledge by virtue of showing how they work and what outcomes they tend to bring about. Are these two ways of looking at scientific explanations compatible with one another and with the manipulationist approach?

The question of the compatibility of the three approaches must be formulated more sharply. Are the three approaches compatible and in what sense? I want to distinguish between two senses:

Compatibility in the weak sense: The three approaches are compatible in that each approach applies in different domains of science.

Compatibility in the strong sense: Uses of different approaches in the same domain would lead to the same conclusions regarding explanatory relations.

I only defend the compatibility in the weak sense. Prima facie, at least, the three approaches are not necessarily mutually exclusive – each one offers a reasonable way of construing explanations. They might be taken as representing indeed three different, but compatible, aspects of scientific

explanation. Since scientific understanding is after all a very complex matter, there is every reason to suppose that it has different dimensions. In other words, there is no a priori reason to assume that a single theory of philosophical explanation must necessarily cover all dimensions of explanatory activity. However, this prima facie contention needs to be elaborated and defended.

The core issue that seems to divide the unification approach on the one hand and the mechanistic and manipulationist approaches on the other seems to be the question whether explanations must necessarily include causes, or in other words whether any genuine explanation has to take into consideration the causes involved. The causal/mechanical approach takes this for granted and goes on to specify how exactly causality is tied to explanation. The unification approach, on the other hand, contends that the concept of causal dependence is derivative from that of explanatory dependence. It is from the 'because' that one can infer the 'cause' and not vice versa. What is distinctive about the unification view is, thus, that it proposes to ground causal claims in claims about explanatory dependency rather than vice versa. This approach accounts for the intuition that appeals to shadows not explaining the heights of towers because shadow heights are causally dependent on tower heights. It suggests that the view of causality in this and similar cases rather stems from an appreciation of the explanatory ordering of beliefs. Put more simply, one can only identify something as a cause because this something provides the explanation of the phenomenon at hand – the concept of causal dependence is derivative from that of explanatory dependence. Adopting a position and making a decision in favor of the primacy of causal or explanatory dependence goes hand in hand with adopting the respective metaphysical commitments and coming to grips with Hume's legacy that causal judgments are epistemologically problematic.

This difference in the approaches seems to be really fundamental since it concerns the thorny metaphysical question about the nature of causality. Although more and more philosophers – surprisingly – hasten to jump on the train of causality in order to reach explanation, cautiousness is necessary. Not all explanation is causal explanation; the most prominent examples of noncausal explanation include mathematical, geometrical, and equilibrium explanation (Sober, 1983). If all these are accepted as genuine cases of explanation, then it is definitely wrong to insist on including causal arguments in every explanatory account. However, this core issue remains, and, in my judgment, constitutes the main dividing line between the unificationist approach on the one hand and the mechanistic and manipulationist approaches on the other, and in the end this is the main reason that a real bridge between them is impossible.

However, the question of their compatibility remains open and should be addressed (Strevens, 2008). It is necessary to take a close look at the scientific practices prevailing in different domains of science in order to inquire whether the three approaches are compatible in the sense that one of them best accommodates the scientific practices in some domains of science and the others accommodate best the scientific practices in other domains of science. Should this be the case, then the compatibility of the three approaches would not refer to the theoretical bridges in the philosophical theory of explanation intended to bring the three approaches closer together, but rather to the domains of application of the three approaches – the compatibility in the weak sense could be defended. I will devote more space to this task and mainly focus on the social sciences.

Compatibility of the Three Approaches of Explanation in the Social Sciences

The picture in the social sciences seems to be very disparate. On the one hand, the most theoretically developed field is probably neoclassical microeconomics, for which the unification approach with its insistence on deductivism seems to offer the best account. On the other hand, in sociology and political science one is confronted with a multitude of theoretical approaches, which do not aim at establishing a global theoretical framework but insist instead on highlighting specific, middle-range causal mechanisms as the means of explaining certain aspects of the social world. The mechanistic approach to explanation can clearly better accommodate these cases. Finally, it seems possible to capture a lot of empirical work carried out in the social sciences with the interventionist account of Jim Woodward. This is especially true for econometrics, which provides the example par excellence of the kind of toolbox used in trying to answer a "what-if-things-had-been-different question," the question that occupies center stage in Woodward's manipulationist account of explanation. I now will elaborate on my claim that each philosophical account of scientific explanation best captures a different domain of social science.

Neoclassical Microeconomic Theory

The standard neoclassical microeconomic theory is based on the theoretical construction of utility maximization. Since the marginalist revolution in the 1870s and the pioneering works of Leon Walras, Carl Menger, and William Stanley Jevons, a theory of price has been devised based on marginal utilities. Marshall's (1890/1920) *Principles of Economics* then provided a systematic account of the interplay between demand and supply on product and factor markets. Today, neoclassical microeconomic theory provides a standard axiomatization of the behavior of households and firms in markets. The general theoretical framework that underlies this neoclassical theory of markets is the rationality hypothesis. The hypothesis of utility maximization plays the fundamental role in driving economic research, and it claims to offer a theoretical account covering all those cases where two or more individuals exchange goods under conditions of scarcity. Neoclassical microeconomic theory offers a global theoretical framework for both a partial analysis of a single market and a total analysis of all markets in an economy, using the utility maximization hypothesis and focusing on the properties of economic equilibrium.

As Mäki (2001) and Mäki and Marchionni (2009) correctly point out, the ideal of explanatory unification is prevalent in economics, and more specifically in neoclassical economic theory. One of the great merits of the theory is supposed to consist precisely in its unifying power, i.e., its ability to subsume a great range of economic phenomena under a unique descriptive and explanatory scheme. Kitcher's (1989, 432) verdict seems to fit exactly to the case of neoclassical

microeconomics: "Science advances our understanding of nature by showing us how to derive descriptions of many phenomena, using the same patterns of derivation over and over again, and, in demonstrating this, it teaches how to reduce the number of types of facts we have to accept as ultimate (or brute)." The unificationist approach to scientific explanation seems unambiguously to capture, thus, the heart of the neoclassical economic enterprise, to derive over and over again a wide range of descriptions of economic phenomena from a standard set of patterns, with the maximization under constraints being the most obvious and prominent one.

Now, neoclassical microeconomic theory is, and has always been, under serious attack. Alternative research programs have always prevailed. Institutional Economics is the most prominent case at hand (Mantzavinos, 2001; Mantzavinos et al., 2004) (with a few Nobel Prizes awarded to a series of leading figures working in this research program), and more recently Behavioral Economics. This is not the place to proceed to the evaluation of the alternative research programs in economics or to present the battery of critical arguments against neoclassical economics that has been shaped and elaborated on by a series of economists and philosophers. What is important here is the following: There is an *opinio communis* among critics and defenders of neoclassical economics alike that one, if not the main, virtue of the approach is its power to unify diverse phenomena under a single descriptive and explanatory scheme. It is due to this specific merit of the theory that it is probably the only piece of social science that is offered in a standardized way in every single introductory textbook taught in every single economics department around the globe.

The ideal of unification has been pushed even further by applying the neoclassical toolbox to the study of phenomena other than the traditional economic ones. Buchanan (Buchanan (1975); Buchanan and Tullock (1962); Brennan and Buchanan (1985)), Downes (1957), and Olson (1965) – just to name a few protagonists of introducing neoclassical economic theory into the study of politics – have given birth to a whole new discipline, Public Choice (Mueller, 2003), which is a consistent step toward a unification of economic and political phenomena. Besides, the same patterns of derivation of neoclassical economics 'are used over and over again' to explain such diverse social phenomena as crime and family (Becker, 1976; Becker and Posner, 2009), and law and sex (Posner, 2010). It is clear that the unificationist theory of explanation can provide a better account and accommodate better the practices of the scientists working within the neoclassical economic theoretical framework than the alternative philosophical theories of explanation. Taking into consideration that neoclassical economic theory avails of a unique reputation amidst the social sciences – rightly or wrongly so is not under dispute here – the unification approach to explanation seems to be tailored to capture the reasons for its popularity.

Social Mechanisms in Political Science

A great deal of political science, when not of a descriptive or purely historical nature, deals with laying bare the working properties of social mechanisms or opening up the black boxes between independent and dependent variables (e.g., Elster, 2007, ch. 2) by identifying the specific causal patterns at work. In comparative politics in political science, for example, the focus of political scientists is to highlight the mechanisms that exhibit a relative constancy across countries and epochs. A prominent piece of theoretical work that aims at discovering a specific social mechanism that I want to briefly present here is Kalyvas's (2006) *The Logic of Violence in Civil Wars*.

Kalyvas differentiates between the broad concept of civil war and the phenomenon of civil war violence. His study is innovative inter alia for not treating violence and war as the same phenomena as has previously been done in the literature, but for focusing on violence within civil wars as a dependent variable. In his model, civil war itself is an exogenous shock onto a society, which can activate invisible networks of grievances among its individuals. His theoretical approach breaks civil war violence down into two basic categories: indiscriminate violence is executed massively, whereas, in contrast, selective violence describes targeted aggression toward individuals identified as enemies with the help of specific local information about their actions. The aim is to provide an explanation of the spatial variance of the dependent variable, i.e., of violence in civil wars – characterized by its barbarism and the fact that victims and executioners used to live together peacefully before the outbreak of the civil war. The independent variable that Kalyvas highlights as the most important is territorial control exercised by opposed fractions. He explains the level of violence in a territory as a function of the degree of control that the warring fractions exert over a particular territory.

The mechanism that is at work starts with individual actors, who are assumed to be rational in their activity in the sense of trying to further their self-interest within a given geographical region. Civil wars are very often warred by means of irregular warfare, and despite the frequency and planning that are involved in indiscriminate violence, the warring fractions soon discover it to be counterproductive. Armed groups soon realize that selective violence better furthers their interest, but then their principal problem becomes the removal of the uncertainty about who the enemy is and who is neutral in an environment where competitors are able to hide behind civilian population. The solution to this problem requires armed groups to collect specific information about individuals, which in turn gives individual noncombatants incentives to cooperate. Since enemies can be hidden among apparent supporters of a community, the exertion of selective violence requires information about specific people, which is most easily collected from individual noncombatants acting as denouncers; and thus selective violence becomes "a *joint* process, created by the actions of both political actors and civilians" (Kalyvas, 2006, p. 209, emphasis in original). The probability of denunciations grows in a nonmonotonical way with the level of control that one side has in a given area since differing levels of control provide different incentives to potential civilian informers and thus leads them to different calculations with respect to the benefits of denunciation. The more control one side has in a given geographical territory, the less the denouncers will face risks of retaliation by the other side and thus the higher will be their propensity to collaborate and provide information – very often because of grievances against specific individuals dating back to the peaceful period. Selective violence is the outcome of the interplay of many individual decisions that take place in

certain social contexts defined precisely within the model. The evidence provided stems from regional data of the Greek Civil War, and it accounts for two-thirds of violence variance, and the validity of the model outside the Greek sample is tested through a great range of both historical and anecdotal accounts about civil wars around the world.

The mechanistic model of explanation can clearly best accommodate such pieces of social scientific research. The aim of this kind of scientific endeavor is not to establish a global theoretical framework and provide the unification of a great range of phenomena, but to insist instead on highlighting specific, middle-range causal mechanisms as the means of explaining certain aspects of the social world. The mechanistic approach to explanation is clearly the appropriate philosophical model in those cases.

Econometrics

Econometrics originally emerged as a field at the intersection of economics, mathematics, and statistics, aiming at the provision of numerical values for the parameters of economic relationships, for example, elasticities, mariginal values, etc. and at the verification or falsification of economic theories. The main insight offered by econometrics is that economic relationships contain a random element, which is typically ignored by economic theory that standardly postulates exact relationships between the various economic magnitudes. Econometrics offers a range of methods for dealing with the random component of economic relationships.

Since the heart of econometrics lies in regression equation models that specify a functional relationship between dependent and independent variables, including also a 'measurement error,' econometric techniques have been included over the years in the toolboxes of other disciplines in the social sciences. Regression equations take the following form:

$$Y = B_1X_1 + B_2X_2 + \cdots + B_nX_n + U$$

$X_1, X_2, \ldots, X_n$ are the independent variables, $B_1, B_2, \ldots, B_n$ are the coefficients, Y is the dependent variable, and U the error term (which makes the model a stochastic one).

Now, such equations cry for a causal interpretation, which can shed light upon the relationship between different variables in a specific setting. This is exactly what the philosophical theory of explanation proposed by Woodward offers: a natural causal interpretation of such regression equations. Each of X_1, X_2, …, X_n are (direct) causes of Y, and these causal relationships are understood as holding for each individual in the population of interest "in the sense that for each such individual (the regression equation) characterizes the response of the value of Y possessed by that individual to some range of interventions that change the values of $X_1, \ldots, X_n$ for that individual. On this interpretation, the error term U also has a causal interpretation: it represents the combined influence of all the other causes of Y besides $X_1, \ldots, X_n$ that are not explicitly represented in (the regression equation)" (Woodward, 2003, p. 321).

A great bulk of applied work in economics and the other social sciences consists in establishing the truth of those kinds of quantitative relationships. The core issue is that social scientists very often do not aspire to establish the truth of general laws, but rather to establish the truth of quantitative relationships that have been tested successfully and hold in specific populations and under specific circumstances. Judged from a God's point of view, those generalizations might be judged insufficient on many grounds; however, scientific knowledge in the social sciences *de facto* consists of such quantitative relationships that are invariant and hold only in specific settings. Neither the unificationist nor the mechanistic approach to explanation can adequately capture these scientific practices. Woodward's manipulationist account on the contrary seems to be tailored to them.

Summarizing, the discussion has shown that there definitely is compatibility between the three philosophical approaches to explanation, but this does not allow them to be synthesized into one approach; rather they are compatible in that they can be applied in different and distinct domains of social scientific knowledge. In other words, they are compatible because they refer to different explanatory enterprises that constitute parts of different domains of social sciences and that are all perfectly legitimate. Insofar the weak compatibility thesis is tenable.

Conclusion: Towards Explanatory Pluralism

Since it is commonly accepted that philosophy of science as a discipline can only be useful if it takes the scientific practices seriously, and it is clearly the case that in different domains different kinds of scientific practices prevail, trying to establish a monolithic philosophical theory of explanation that is supposedly good for everything cannot be an acceptable strategy. In a nutshell, the goal of a philosophical account of explanation should not be to capture the explanatory relation, but rather to capture the many ways in which explanations are provided in the different domains of science.

The position that emerges then and that I wish to adopt is that of an explanatory pluralism. This is a pluralistic account that allows for different ideal types of explanation, i.e., different exemplary accounts of what an explanation consists of, which are good as means of classification of different types of explanatory activities that are offered in different domains of the (social) sciences. This explanatory pluralism is different from the explanatory ecumenism that Jackson and Pettit (1992) endorse insofar as it is independent of any type of commitment to causality. In other words, I disagree with what Jackson and Pettit call 'causal fundamentalism,' i.e., the view that every explanation must provide information on the causal history of what is to be explained (a view also endorsed by Lewis (1986, p. 217) in his famous verdict that "to explain an event is to provide some information about its causal history"). The explanatory pluralism that I propose is a genuinely pluralistic position that makes as few commitments as possible to causality (and other metaphysical issues). It does not preclude that explanations in some domains of science are offered, debated, and criticized in terms of figuring out causal patterns, processes, or mechanisms; it also permits scientific explanations that provide scientific understanding by, for example, unifying phenomena without invoking causes.

The main danger for a defender of such a position is the possibility of sliding into a pure sociological theory of scientific explanation that just provides descriptions of different explanatory practices or, even worse, to make such a position serve a purely apologetic function by providing ex post legitimization

of any and/or all explanatory scientific practices. However, philosophy of science has a normative function to serve, so that a philosophical theory of explanation that intends to be pluralistic must clearly accommodate normative considerations. Working out the normative dimension of explanatory pluralism is clearly a desideratum. However, any kind of normative considerations cannot be formulated *in abstracto*, but must be founded on the existing scientific practices. The aim of this article has been the moderate one of establishing the claim that the philosophical theories of explanation currently on offer do not exclude each other but can rather capture some of those practices and thus of reorienting the discussion toward the feasibility of the position of explanatory pluralism.

Abstract

The origins and growth of the sociology of scientific knowledge (SSK) are described along with some recent developments. The sociology of *scientific* knowledge is distinguished from the sociology of knowledge by its readiness to apply the latter's insights to science and technology whereas before they had been treated as immune – islands of rational thought with an 'internal' dynamic only. Different philosophical flavors of SSK are distinguished.

The sociology of knowledge originally treated the sciences as immune to social analysis, but from the 1970s, the very content of scientific knowledge has been treated as a social product – at least in part. Thinking in sociology of knowledge terms, this transformation could be seen as belonging to the revolution of ideas that took place in the West in the affluent 1960s, but the origins of the thought that informed the new movement goes back further. Sociology of scientific knowledge (SSK) introduced new concepts, such as the need to treat true and false ideas symmetrically in terms of social analysis. Once truth was no longer taken to determine belief, it became possible to explore the way scientific beliefs were actually formed. Experimental findings were shown to be 'interpretatively flexible' and less determining than had been thought. Scientific disputes reached 'closure' only through a variety of means beyond theory and experiment. Trust and personal judgment turned out to have central roles in the production of scientific knowledge. Different approaches to SSK have widely differing political and philosophical consequences, philosophical radicalism not always coinciding with political significance.

Origins

The central concern of the sociology of knowledge is the idea that what people take to be certain is an accident of the society in which they are born and brought up. It is obvious that religious or political truths are largely affected by their social settings. If the truths are moral, then such relativism is more troubling. But if the truths are scientific, then the idea of social determination is widely regarded as subversive, or self-defeating – since the science that purports to show that science is socially situated is itself socially situated. The sociology of knowledge, as formulated by Mannheim (1936), avoided these dangerous and dizzying consequences by putting settled scientific and mathematical knowledge in a special category; other kinds of knowledge had roots in society but the knowledge of the natural sciences was governed by nature or logic. Scientific method, then, when properly applied, would insulate scientists from social influences and their knowledge should be more true and more universal than other kinds of knowledge. From the early 1970s, however, groups of sociologists, philosophers, historians, and other social scientists began programs of analysis and research, which treated scientific knowledge as comparable with other kinds of knowledge. Their work broke down the barrier between ordinary knowledge and scientific knowledge.

The post-1970s SSK, which included major contributions from historians of science, shows us how to understand the impact of social influences on all knowledge. We can use the field's own approach to query its intellectual origins. A suitable model is a well-known paper by historian Paul Forman (1971), who argued that the rise of quantum theory owed much to the 'Weltanschauung' of Weimar Germany. In the same way, it could be argued that the 1960s saw the growth of postwar prosperity in Europe, which allowed the development of new markets with young people becoming powerful consumers of goods and producers of culture – much of it consisting of a rebellion against traditional forms of expression. The 1960s also saw the development of the birth control pill, making possible a (temporary) breakdown of sexual mores. During that era, experiments with perception-affecting drugs led to questioning of consensual reality, while protests against the Vietnam War threatened old lines of institutional authority. The new order had its counterpart in academe. Antipsychiatry questioned the barriers between the sane and the insane, while in Europe at least, romanticized versions of Marxism dominated debate. SSK's questioning of the traditional authority of science can plausibly be seen as a product of this social ferment.

The emblematic book of the period as far as science was concerned was Thomas Kuhn's (1962) *The Structure of Scientific Revolutions*. Kuhn's book was influential in helping to reinforce the intellectual atmosphere in which radical ideas about science could flourish. Kuhn's notions of the incommensurability of paradigms, and of paradigm revolution, provided a way of thinking about scientific knowledge as a product as much of culture as of nature. The book was not widely discussed until late in the 1960s, when the new social movements were at their height, and this adds force to the argument.

Philosophy of science in the early 1970s was also affected by this turn. The so-called 'Popper–Kuhn' debate (Lakatos and Musgrave, 1970) pitted Karl Popper's (e.g., 1959) notion that scientific theories could be falsified with near certainty, even if they could not be proved, against Thomas Kuhn's (1961, 1962) claim that what was taken to be true or false varied in response to sudden revolutions in scientific world view. The 'Duhem–Quine thesis' (Losee, 1980) showed that scientific theories were supported by networks of observations, such that no one observation could threaten any other part of the network directly. Imre Lakatos's (1976[1963]) brilliant analysis of the

history of Euler's theorem showed that falsification of a theory was only one choice when faced with apparently recalcitrant observations. Lakatos's work was particularly attractive to the social analyst of science because it dealt with the detailed history of a real case rather than an ideal-typical case designed to illustrate general principles. Lakatos was showing how mathematicians argued (or could have argued in principle). This was the world of philosophical activity into which the SSK was born.

Like any other group of knowers, sociologists of scientific knowledge prefer models of the genesis of their own ideas which reflect their self-image as 'rational creatures' or, in Mannheim's phrase, 'free floating intellectuals.' In these models Kuhn plays a much smaller role. There are two intellectual stories. One turns on Ludwik Fleck's (1979 [1935]) *Genesis and Development of a Scientific Fact*, which Kuhn cites in the preface of his 1962 book, and which already contained many of the key ideas found therein. Furthermore, Fleck's book anticipated the developments in SSK, which came in the 1970s in that, unlike *The Structure of Scientific Revolutions*, it included a case study of a contemporaneous scientific episode: Fleck's own research on the Wasserman reaction for the diagnosis of syphilis. Indeed, Fleck's book remains unique in sociology of science in that his social analysis was of a pioneering piece of scientific research, which he himself was pioneering. Thus, it is the most perfect piece of participant observation yet done in the social study of scientific knowledge.

Fleck's book, however, was not widely known until many years after Kuhn's was published, and not until long after the SSK had established its own way of doing things. Fleck, then, was the first to set out some of the crucial ideas for SSK, but he had little influence on the new movement except through his influence on Kuhn. For his part, Kuhn helped open up the social and intellectual space for what came after, rather than providing intellectual foundations or methodological principles; in other words, Kuhn provided the intellectual space but not, to use his own term, the paradigm.

The origin of SSK's intellectual and methodological *paradigm* has to be understood by looking at more direct influences. In the 1970s a group of philosophers, concerned with defending science against what they perceived as its critics, put forward the argument that sociological analysis could be applied only to knowledge that was in error, whereas true knowledge remained insulated from social forces. The intellectual source for the sociologists who inspired these initial attacks and fought against them was yet another philosopher, Ludwig Wittgenstein, whose work was central to the anthropological debate about whether there were universal standards of rationality (Wilson, 1970). Readings of Wittgenstein's later philosophy (Winch, 1958; Wittgenstein, 1953, 1956) produced the crucial theoretical resource for the work in SSK that had its origins in the mid-1970s. The 'Edinburgh School' and its 'Strong Programme' argued on philosophical grounds that 'symmetrical analysis' – analysis that treated true knowledge and false knowledge equally – was possible. Historical studies conducted in this framework showed how social influence affected scientific conclusions, in science in general, in early studies of the brain, in the development of statistics, and in high-energy physics (Bloor, 1973, 1976; Barnes, 1974; Shapin, 1979; MacKenzie, 1981; Pickering, 1984). Independently, a group at the University of Bath applied Wittgensteinian ideas to contemporary episodes of science, particularly controversies in physics and the fringe sciences, and developed the methodology of interviewing participants in such controversies at networks of competing scientific centers. Its program became known as the 'Empirical Programme of Relativism' (EPOR; Collins, 1975, 1985; Pinch, 1977, 1986; Travis, 1980, 1981). These approaches were to become quite widely adopted in the early years of SSK.

As the 1970s turned into the 1980s other groups, more strongly influenced by anthropological practice, entered and influenced the field. The Edinburgh–Bath approach was influenced by anthropology in that much of the discussion of the meaning of Wittgensteinian philosophy for the social sciences turned on questions that had to do with the knowledge of isolated 'tribes' and its relationship to Western knowledge. The newer contributors, however, aligned themselves with anthropology. Their work founded the tradition of 'laboratory studies.' In the Strong Programme, the source of material tended to be historical archives; in EPOR, the method was interviews with members of the 'core set' of scientific laboratories contributing to a scientific controversy; in laboratory studies, the method was a long sojourn in, or deep study of, a single laboratory (Latour and Woolgar, 1979; Knorr Cetina, 1981). The setting for the laboratory studies tended to be the life sciences rather than the hard sciences or fringe sciences.

Another important input was the interpretive tradition in sociology associated with phenomenology and ethnomethodology. Indeed the term 'social construction' is a widely used description of the approach: 'social construction of scientific knowledge' was taken from the title of a well-known book by Peter Berger and Thomas Luckmann (1967) – though Berger's *Invitation to Sociology* (1963) probably had more direct impact on the field. Ethnomethodology strongly influenced all those who practiced SSK and especially the detailed analyses of scientific practice such as those by Lynch (1985) (but written much earlier than its publication date), Woolgar (1976), and especially the move of some authors into what became known as 'discourse analysis' (Knorr Cetina and Mulkay, 1983).

As the 1980s turned into the 1990s, the concentration on language that began with the move to discourse analysis helped SSK to appear to be part of the much larger movement known as 'postmodernism.' The influence of French philosophers of literature and culture such as Derrida became marked. Since then 'cultural studies of science,' which share with SSK what could broadly be called a 'social constructivist' approach to science, have attracted large numbers of followers in the humanities as well as the social sciences. The respective methods and, more especially, the attitudes toward methodology make it possible to separate cultural studies from SSK. Crucially, SSK practitioners still take natural science as the touchstone where matters of method are concerned, though the model of science is very far from the narrow statistically based notion of science that informed the 'scientific sociology' of the 1950s and early 1960s, and continues to dominate much mainstream sociological practice in the United States. SSK stresses the more general values of careful empirical observation and

repeatability. Cultural studies, in contrast, take philosophical literary criticism, or semiotics, as the model to be followed.

Concepts

Among sociology's traditional topics was the study of the social factors that affected scientists' choices of research topics. The SSK, however, took it that the *outcomes* of research projects also were affected by their social setting. SSK showed that theoretical and experimental procedures did not determine, or fully determine, the conclusions of scientific research. The philosophical ideas described above provided an important starting point, but sociologists of scientific knowledge developed their own concepts, which were set in the working world of the scientist rather than the abstract world of the philosopher. One strand of research showed how difficult it was to transfer the skills of physics experimentation between settings; showing further that it was even harder to know that such skills had been transferred, and even harder still to know when an experiment had been satisfactorily completed. This meant that scientists did not know with certainty when negative results from an experiment should be taken to contradict a positive outcome. This argument became known as 'the experimenter's regress' (Collins, 1975, 1985), and it revealed the scope for 'interpretive flexibility' regarding the outcomes of passages of experimentation and theorization. It also means that even while SSK proponents stress the importance of empirical research and repeatability, they are aware that, by themselves, such procedures cannot turn disputed knowledge into certainty in either the natural or social sciences.

Even if experimental science produced widely accepted data, as Pinch (1981) showed, the 'evidential significance' of such data could vary and the same finding could count as revolutionary or insignificant depending upon how it was subsequently characterized. Sociological studies also described the processes that link the disordered activities of the laboratory with the orderly 'findings' (Latour and Woolgar, 1979; Knorr Cetina, 1981) or 'discoveries' (Brannigan, 1981) reported – or constructed – in the published literature. Latour and Woolgar demonstrated the way that 'modalities' – words and phrases that qualified a finding or referred to the particular time and place of its generation – were successively stripped from publications as the finding became established. What they called 'inversion' was the way the stripping of the modalities, and similar processes, comprised the establishment of the finding – a reversal of the accepted direction of the causal arrow. It was also shown that, with some exceptions, 'distance lends enchantment,' that is, certainty about scientific outcomes tends to increase as the interpreter's distance from the laboratory increases (Collins, 1985; MacKenzie, 1998). This concept explained why commentators' accounts often seemed far more confident than the reports of the scientists themselves, and explained much about the way scientific knowledge was diffused beyond the specialists.

Mechanisms of 'closure' were described through which potentially open-ended disputes were brought to a close around a particular interpretation. Different approaches to closure were taken, with EPOR concentrating on fringe sciences, the 'French School' of Actor–Network Theory (ANT) concentrating on the interplay of human and nonhuman 'actors' within networks (Latour, 1987), and the 'Edinburgh School' concentrating on large-scale political influences on the content of ideas (Shapin, 1979; MacKenzie, 1981; Shapin and Schaffer, 1985). More recently, work on closure has broadened to include studies in the social construction of technology, which applied the EPOR to technology and is widely known by the acronym, SCOT, the public understanding of science, and law and science.

Significance

The early 1990s were characterized by what became known as the 'science wars.' Scientists, along with some philosophers, attacked science studies for its misconceptions of science and complete misunderstanding of how science works. They were worried that SSK and related analyses would weaken science. That the criticism was more of a 'war' than a proper debate can be seen from some of the more ridiculous but oft-repeated claims, such as that the critics of science had no idea of how an experiment worked. This might have been true of some of those who came from an arts and humanities background, but even a superficial reading of the works that were being attacked as icons of the movement, such as *The Golem* series of books (particularly Collins and Pinch, 1993), would have revealed that the science being discussed was thoroughly understood. Fortunately, the more outrageous of these attacks were to die away, helped by at least a partial meeting of minds of natural and social scientists represented in books such as *The One Culture* (2001; coedited by Labinger (a chemist) and Collins). The science warriors made a blanket attack on science studies, obscuring that both the philosophical and political radicalism of the social analysis of science varies from program to program and study to study. Today, it has begun to seem as though some of the science warriors' concerns might have been justified, even if the means of attack were not. Thus science and technology studies, which is based on SSK and the related programs, can have an antiscience and antitechnology flavor, as well as a tendency to favor the views of the general public on technical matters over the views of experts.

The science warriors' attacks on SSK focused on its relativism. But even this relativism is not at all uniform. For example, 'epistemological relativism' implies that one social group's way of justifying its knowledge is as good as another's and that there is no external vantage point from which to judge between them; accordingly, all that can be known is known only from the point of view of one social group or another. Ontological relativism is the view that, in social groups such as those described above, reality itself is different. A combination of epistemological and/or ontological relativism can be referred to as 'philosophical relativism.' This attitude is nicely captured by McHugh in the following quotation: "We must accept that there are no adequate grounds for establishing criteria of truth except the grounds that are employed to grant or concede it – truth is conceivable only as a socially organized upshot of contingent courses of linguistic, conceptual and social behaviour" (1971: 329). Philosophical relativism, then, is a philosophically radical viewpoint.

A still more philosophically radical position is actor (or actant) network theory most closely associated with Michel Callon and Bruno Latour. The approach was first signaled by Latour and Woolgar when, in 1986, they changed the subtitle of *Laboratory Life* (Latour and Woolgar, 1979) from *The Social Construction of Scientific Facts* to *The Construction of Scientific Facts* (1986) so as to signify that the 'social' in their view no longer deserved special mention in the shaping of scientific knowledge. Subsequently, as Callon and Latour developed their ideas, scientific facts came to be seen as emerging from the interplay of 'actants' in the 'text,' of life – suggesting that ANT should most properly be included under cultural studies of science rather than SSK. Within Callon and Latour's 'text,' terms such as 'social' and 'natural' are themselves outcomes of the interplay of actants rather than original causes. Therefore, to draw attention to the social as a special factor is to begin the discussion at too low a level of generality. Under this approach, 'constructivism' has ceased to be *social* and among the actants nonhumans are given as much reality-forming agency as humans (Callon, 1986). The philosophical radicalness of ANT is clear in its refusal to accept even the distinction between human and nonhuman as primary. ANT has been enormously successful, in part, perhaps, because it enabled humanities scholars to produce literary critiques of science without the back-breaking precondition of participating in the scientific form of life being analyzed.

Methodological relativism, by contrast, says nothing direct about reality or the justification of knowledge. Methodological relativism is an attitude of mind recommended by some of those who practice SSK; it says that the sociologist or historian of science should act as though the beliefs about reality of any of the competing groups being investigated are not caused by the reality itself. The intention is to limit analysis to the kinds of cause of scientific beliefs that are located in the domain of the social. Methodological relativism is meant to push exploration of the social causes of belief to the limit without having to cut off the investigation with the argument that a belief was widely accepted because it was rational. Methodological relativism is, then, not at all radical as a philosophy, it is a (social) scientific method.

Methodological relativism may be considered to be time bounded if it claims only that scientific procedures are often inconclusive in the short term, whatever the deeper significance of any consensus about results that is attained in the long term. This kind of relativism, which makes no strong philosophical claim beyond that fact that relativism is supportable as a methodology, is all that is needed to support much current social analysis of contemporary science, especially controversies that have impact on the public domain (e.g., Collins and Pinch, 1993; Richards, 1991; Epstein, 1996).

The relationship between philosophical radicalism and political radicalism is, however, perverse. Time-bounded relativism has consequences for contemporary scientific controversies, such as those that engage environmentalists and the like: it has this power because it shows that, contrary to the way scientific controversies are treated in textbooks and many popular accounts, the 'short-term' period before scientific disputes are resolved is often many decades long. The empirical and analytic tools of SSK can explain why such disputes are sustained, and they suggest that we should not expect speedy science-based resolutions to our current technological dilemmas. Following this line of thinking, it can be argued that the decision-making power once monopolized by scientific experts should be more widely shared (Wynne, 1987). Methodological relativism, which is philosophically quietist, tends to be disturbing to the scientific community as it blatantly sets aside scientific consensus, however well established. To go to the other extreme, ANT, the most philosophically radical position in science and technology studies, by removing humans from the central position they hold in *social* constructivism, recreates a relationship between scientists and their nonhuman objects of study, which is similar to that which held before the revolutions of the 1960s and 1970s (Collins and Yearley, 1992; Callon and Latour, 1992; Fuller, 2000). What about philosophical relativism? Scientists and philosophers often conflate methodological and philosophical relativism, believing that the later justifies nonscientific beliefs or fringe sciences, such as parapsychology, whereas the aim is to analyze the social process by which they become rejected without assuming that the content of the science is the explanation. SSK, of course, argues that as knowledge moves from its seat of creation to a wider audience, it tends to be stripped down and simplified, so it is not surprising that the subtleties of the various relativist positions have escaped the more outspoken critics of the social analysis of scientific knowledge.

In recent years an attempt has been made to reconcile the relativism of SSK and its findings with the central role of science in society, under what has been termed a Third Wave of Science Studies (Collins and Evans, 2002, 2007). The aim has been to maintain a notion of expertise in the face of the vulnerability of truth to sociological deconstruction. To the extent that the ideas of the Third Wave are successful we can both have our cake of relativist SSK and eat it in the form of expertise; this should mean a final end to any lingering suspicion about the dangerous potential of the sociological analysis of scientific knowledge.

Scientific Misconduct, Plagiarism, and Institutional Control of Misconduct

Ragnvald Kalleberg, University of Oslo, Oslo, Norway

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Scientific misconduct refers to fraud, to serious violations of the internal research ethical norms related to the truth-commitment of science. The three most common examples used to illustrate such misconduct, are fabrication of fictitious data, falsification of data and methods, and plagiarism. The next section is focused on the historical emergence of modern research ethics in early modernity, as an integrated element in the scientific revolution. Robert Merton labeled this system of values and norms "the ethos of science." As aset of institutional imperatives it has perhaps been the most efficient system of internal self-control invented in the modern world. The last section deals with developments in research ethics after World War II. Before World War II institutional control of misconduct was informal, based on the self-correcting power of individuals and groups. Today the traditional system of self-regulation is more explicitly cultivated and supervised, complemented with procedures and committees on higher levels, such as at the level of organizations. The task of new procedures and institutions is to comple guard, control, stimulate and further develop traditional self-regulation, not to replace it.

The Phenomenon of Scientific Misconduct

What kinds of malpractices are covered by the concept of 'scientific misconduct'? There is no general definition and terminology agreed on across disciplines, institutions, and countries. Definitions vary in breadth. In its policy document on research integrity Johns Hopkins University in 1988 used a relatively narrow definition: "Research fraud is the intentional falsification or fabrication of data or results, plagiarism, misconduct in the application of research procedures so as to bias results, or other deceptive research or reporting practices" (Steneck, 1994, p. 318). The European Science Foundation (ESF, 2011) also focuses on other 'forms of misconduct,' generally identified as 'failure to meet clear ethical and legal requirements.' The ESF gives examples of serious deviations such as "misrepresentation of interests, breach of confidentiality, lack of informed consent and abuse of research subjects or materials" (Section 1.3).

It can be useful to order the norms and values of research in four groups: (1) Internal norms about the production and testing of knowledge claims. These are norms regulating the inner workings of research communities in their search for valid knowledge. Such norms also include those safeguarding the autonomy of researchers and research institutions. (2) More external norms, regulating the relationships between researchers and living beings studied, for instance individual persons, groups, institutions, and animals. (3) Norms regulating the relations to those financing and using research. (4) Norms relevant for the communication of scientific knowledge to those outside of the specialized research fields – researchers in other specialized fields included. We can label this fourth subgroup of norms the cultural and democratic obligations of science (Kalleberg, 2014).

Norms and values in the different groups are related to each other and partly overlapping. They are all relevant for the social and behavioral sciences. Good referencing behavior, free and informed consent from those studied, conflict of interests, and appropriate dissemination of scientific knowledge to those outside of a research field are examples from each group of norms. Within the social sciences there has been much discussion about norms regulating the relationships to those studied, for instance in well-known social psychological experiments, such as Stanley Milgram's authority experiments and Philip Zimbardo's prison experiment. We can label serious violations of each type of norms as 'scientific misconduct.' In this article the expression 'scientific misconduct' is used in a more narrow meaning, primarily referring to serious violations of norms in the first group. When such norms are violated, words like fraud and dishonesty are often used. Norms and values in this group have to do with the main task of scientific and scholarly activity, its truth commitment.

There is general agreement about examples of major violations of the truth and truthfulness commitment of science. Three types of violations are regularly mentioned, often talked about as FFP. The acronym refers to fabrication of fictitious data, falsification of data and methods, and plagiarism. During the last quarter of a century several misconduct cases have been uncovered and have got much publicity. The best known cases have taken place at excellent research institutions in North America, Europe, and Asia (for some well-known cases, see Anderson et al., 2013, pp. 229–231). It is usual that such cases contain several types of misconduct, such as fabrication, falsification, and plagiarism, and also less serious violations of norms.

Most empirical studies of misconduct have been about the biomedical sciences, and most have been focused on researchers in the United States. There are, however, no convincing reasons to assume that the social sciences are special with regard to scientific misconduct. Serious misconduct and questionable practices have also been documented in these disciplines (see for instance Israel and Hay, 2006; Necker, 2014).

Fabrication refers to fabrication of fictitious data and results, whereas falsification refers to inappropriate manipulation of data, methods, and results (see for instance Israel and Hay, 2006, Chapter 8). Plagiarism concerns authorship. In the *Oxford English Dictionary*, plagiarism is defined as the "action or practice of taking someone else's work, idea, etc., and

passing it off as one's own." Obviously, the criticizable element is not to use the ideas and words of others, but to present them as ones own. Posner (2007, p. 6) identifies plagiarism as a type of 'intellectual fraud' and gives the following, more elaborate definition: "unauthorized copying that the copier claims (whether explicitly or implicitly, and whether deliberately or carelessly) is original with him /sic/ and the claim causes the copier's audience to behave otherwise than it would if it knew the truth." (For definitions of plagiarism and a typology of plagiarism, see Weber-Wulff, 2014, pp. 3–14.)

In Europe, some cases of plagiarism have become widely known during the past years, due to the fact that leading politicians have been forced to leave their positions because plagiarism was discovered in their doctoral dissertations. The two most spectacular cases have been that of the German Minister of Defense in 2011, and the German Minister of Education of Research in 2013 (Weber-Wulff, 2014, pp. 29–31, 57, 58).

Fabrication, falsification, and plagiarism do not represent an exhaustive typology of violations related to the truth and honesty commitment of science. Failure to report conflict of interest, fictitious authorship (so-called gift and ghost authorship), change of design or results because of pressure from institutions financing the research are examples of related violations. If we underline originality as a basic internal value in science, phenomena such as *salamisation* (to divide results up in so small bits as possible in order to increase the number of publications) and self-plagiarism would also be relevant examples.

Scientific and scholarly research is an institutional phenomenon, regulated by norms and values practiced within scientific networks. Such communities often include researchers and research groups spread out around the globe. Norms regulating research ethics consequently also refer to sets of norms and values of a transnational and institutional character, and not only to the practices and ideals of individual researchers in a certain location. There can be no private science or scientific knowledge, nor a science based on dignified sages disseminating esoteric knowledge that is not to be controlled by competent and independent peers. Peer review and replication of results from others are typical examples of this institutional character. Ziman (2000, p. 4) gives this characterization of the institution of science: "Although research *scientists* often have a great deal of freedom in what they do and how they do it, their individual thoughts and actions only have scientific meaning in these larger schemes. Like many facts of life, this is so obvious that it was for long overlooked … The sociological dimension is thus fundamental to our picture." It is still regularly overlooked by researchers and institutions when the focus is on research ethics. But misconduct, or good conduct, is also an institutional phenomenon, not only a matter of the morality of individual researchers.

Widely known cases of misconduct are often identified with only one name, the main person responsible for the misconduct, the single bad apple in a big basket of good apples. In investigations of misconduct cases, however, also several other problems in the relevant scientific community are regularly discovered. They can be identified as system problems or as questionable research practices (QRP) (see Steneck, 2006, pp. 59–61). Examples are sloppy control by coauthors, not thorough enough checking by opponents, advisors, and reviewers, and lack of relevant teaching and mentoring in institutions. Cases of misconduct regularly go hand in hand with questionable practices. There are also examples of institutions covering up misconduct instead of uncovering, handling, and preventing it. This is a kind of serious institutional misconduct. Institutions should instead establish research ethical committees, install procedures informing about where and how to report suspicion of possible misconduct, develop routines for protection of whistleblowers, procedures for handling of misconduct cases, and programs for promoting good conduct and preventing misconduct.

The Emergence of an Ethos of Science and Institutionalized Self-Regulation

The most influential analysis of the ethics of research as an institutional phenomenon where researchers correct each other has been given by Robert Merton. He labeled the phenomenon 'the ethos of science,' referring primarily to the internal norms and values connected to the truth commitment of science. He first published his analysis in two small articles (Merton, 1938, 1942), later followed by several others (as Merton, 1957). His analysis was both based on an extensive historical understanding of the emergence of modern science in the seventeenth century, and reflections based on the undermining and destruction of the ethos of science in the twentieth century, by market forces, nationalism, Nazism, and Communism (Kalleberg, 2007; Enebakk, 2007).

Merton identified the ethos of science like this: "The ethos of science is that affectively toned complex of values and norms which is held to be binding on the man /sic/ of science" (1942, pp. 268, 269; 1938, p. 258). This seminal definition was characterized by the triple perspective of sociological imagination (see Mills, 1959), comprising the interplay of *individuals* and *institutions* embedded in *historical processes* (biographies, traditions). To underline this sociological perspective Merton used the expression 'institutional imperative' as a synonym for 'norm.' The problem with several later definitions of research ethical norms, including many who criticized Merton, has been a too narrow orientation only to individuals and their ideals (or scientific conscience), not at the same time seeing the institutional framework disciplining its members, and the tensions between norms and counter-norms, including the complexity of role-sets embedded in evolving fields of research (Merton, 1963; Kalleberg, 2014).

Merton operated with a traditional, sociological typology of social norms. "The norms are expressed in the form of prescriptions, proscriptions, preferences and permissions" (1942, p.269). The norms and values of the ethos of science are in operation as a set of shared and internalized norms and values, institutional imperatives, characterizing well-functioning scientific communities. Merton did not claim that his typology was exhaustive, nor that the different types were exclusive. They are clearly internally related, partly overlapping each other.

Merton's scientistic interpretation of norms in science, basing them on emotions and not reasons, is not tenable. But that can be corrected at the same time as one preserves the superior insights and realism in his analysis (see Kalleberg, 2007, 2009). Merton's contributions illustrate

a typical phenomenon in the social and cultural sciences: classics are not only of historical interests, but also keep on being of contemporary and systematic interest (see Calhoun, 2010).

The ethos of science in Merton's conception can be presented as a set of six norms, the CUDOSH-norms: Communalism, Universalism, Disinterestedness, Originality, Skepticism and Humility (see Kalleberg, 2007, p. 141, 142). *Communalism* refers to the fact that scientific activity is a sociological phenomenon; there can be no isolated, private science. Knowledge and insight have to be published, made public, in order to be tested and recognized by the collective of peers. "Property rights in science are whittled down to a bare minimum by the rationale of the scientific ethic" (Merton, 1942, p. 273). *Universalism* concerns issues of scientific validity and refers to "the canon that truth claims, whatever their source, are to be subjected to *pre-established impersonal criteria*; consonant with observation and with previously confirmed knowledge" (Merton, 1942, p. 269, italics in original). This institutional imperative can also be characterized as the pursuit of truth, the truth-commitment of science. In a later article Merton explained the relatively few cases of scientific fraud, as compared to other fields, by the institutional "emphasis on the value of truth by whomsoever it is found, and a commitment to the disinterested pursuit of truth" (Merton, 1957, p. 321). *Disinterestedness* concerns impartiality in posing of questions, collection and interpretation of data, and impartiality in argumentation. Science is done for the sake of valid and reliable knowledge.

Originality requires that contributors in well-functioning scientific communities are obliged to present new knowledge and insight, and not only preserve the knowledge of a tradition. As a historical sociologist of the seventeenth century scientific revolution, Merton had a keen eye for identifying the historically new in the insistence on originality. *Skepticism* refers to the obligation to check the validity of documentation and argumentation, not just believing what authors claim. Skepticism became institutionalized in many ways, two of them being the scrutiny of peers reading the contributions and the mechanism of peer review. The basic precept can be formulated like this: only reliable documentation and consistent argumentation shall influence the formation of opinions in well-functioning scientific communities. *Humility* refers to the institutional obligation to understand how little each researcher and discipline understand of a complex reality, and how dependent each individual researcher is on the transnational community of scholars. This intellectual dependence does not only include contemporaries, but also earlier and coming generations. The age-old metaphor often used to convey the meaning of scientific humility in this strict meaning, is the following – here quoted as expressed by one of the greatest scientists of all time, Isaac Newton: "If I have seen farther it is by standing on the shoulders of giants" (Merton, 1942, p. 274, 275).

The ethos of science – like other institutional ethoses, for instance the protestant work ethic (Weber) – does not have to be codified in order to influence action and interaction within research groups and disciplines. The research ethic of science can be characterized as the oldest internal control system in the modern world, as old as modern science. Scientific communities are unthinkable without it; research ethics is internal to science. For Merton, there was little doubt that all in all the amount of fraud was smaller within the social system of science than in other institutions in a modern society. The relatively small amount of deviance in science is due to an institutional trait, its high degree of transparency. If one should try to understand the phenomenon strictly individualistically, without sociological imagination, one would have to rely on an unrealistic presupposition of researchers as moral superbeings. Merton (1957, p. 311) gave this general explanation for the effectiveness of this kind of interactional self-correction:

> Scientific research is typically, if not always, under the exacting scrutiny of fellow experts, involving as it usually, though not always does, the verifiability of results by others. Scientific inquiry is in effect subject to rigorous policing, to a degree perhaps unparalleled in any other field of human activity. Personal honesty is supported by the public and testable character of science.

With the historical emergence of the ethos of science came also violations of those norms and corresponding conflicts. Merton (1957) mentions several examples of fraud in the history science, some of them based on the well-known book by Babbage (1830) on fraud in science. Merton's most detailed discussions of scientific misconduct were focused on plagiarism and priority struggles. When the requirement for originality emerged as part of the scientific revolution, also the first struggles about priority and plagiarism also emerged. An early example is the bitter conflict between Newton and Leibnitz about the invention of the calculus (Merton, 1957, pp. 314, 315). Merton also noted the possible distorting effects of the institutional obligation of originality "in many academic institutions, to transform the sheer number of publications into a ritualized measure of scientific or scholarly accomplishment" (1957, p. 326).

Codification and Institutional Regulation of Research Ethics after World War II

Before World War II institutional control of research ethical norms was informal, based on the self-correcting power of scientific communities. Extensive codification of research ethics and institutional strategies to handle misconduct and promote research integrity, are developments characteristic of the period after World War II. The development came first in medical ethics, oriented to the more external norms of science, focused on the protection of individuals studied. A second wave started in the 1980s in the United States, focused on fraud and deception, concerned with violations of the first set of research ethical norms regulating the inner workings of scientific communities.

A classic sociological insight, associated with the work of Emile Durkheim, can be articulated like this: deviation from a norm can make visible and strengthen that same norm. Merton expressed it like this: "Yet this very deviation from the norm of universalism actually presupposed the legitimacy of the norm … in the process of contemning their violation, the mores are reaffirmed" (Merton, 1942, p. 271). It is worth noting that Merton's (1938, 1942) articles actually were self-exemplifying. He understood that the emerging anti-Semitism in Germany

after World War I perverted leading scientists and institutions, also before Hitler came to power in 1933. For instance, Nobel Prize winners in physics (Philipp Lenard, Johannes Stark) in the early 1920s rejected the work of Einstein because it was produced by a Jew ('Jewish' vs 'Aryan' physics) (Walker, 1995, Chapter 2). Such a violation of the norm of universalism in the world's leading science nation shocked the young American sociologist. He felt compelled to explicate the norms in order to identify, criticize, and correct the misconduct. Karl Popper once characterized his *The Open Society and Its Enemies* as his war effort, his intellectual contribution to promote freedom and democracy. Merton's contributions on the ethos of science can be characterized in the same way.

Violation of basic norms in science, such as fabrication of fictitious data and falsification of data, is dramatic and destructive, arousing strong emotions of anger and sorrow. But cases of scientific misconduct can help science institutions to better see the norms and their importance, and safeguard them institutionally. The strong emotional reactions to such violations can have a cognitive function in such socio-cognitive processes (Kalleberg, 2009, pp. 259–262).

The history of research ethics after World War II confirms the general sociological insight about violations also strengthening values violated. Widespread codification of the ethos was first developed after World War II and the atrocities of German medical doctors during the Nazi period. It started with the so-called Doctors' Trial, taking place in Nuremberg in 1946–47. The defendants were medical doctors. They were convicted because of cruel experimentation and murder of prisoners in concentration camps. The trial led to the *Nuremberg Code* in 1947. The focus was on the more external norms regulating the relationships between researchers and those studied. One central guideline explicated for medical research, was the requirement of free and informed consent from patients and other persons participating.

The World Medical Association (WMA) was established in 1947. After 10 years of preparation, the Association in 1964 adopted *The Declaration of Helsinki*. It was built on the Nuremberg code and has established itself as the best known and most influential statement for medical ethics concerning informing and protecting human beings participating in such research. This code has influenced legislation in the member countries of WMA. The US *Belmont Report* (1978) was produced by the 'National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research.' It came as a response to serious cases of missing or inadequate information of research subjects. A fourth code was developed by the *Council for International Organizations of Medical Sciences*. This code is focused on guidelines for international medical research, also involving participation by less developed countries. Guideline 2 is about review committees – be they located on the institutional, local, regional, national, or international level. All proposals "to conduct research involving human subjects must be submitted for review of their scientific merit and ethical acceptability to one or more scientific review and ethical review committees." Projects must be approved before start-up (on these four codes, see Israel and Hay, 2006, Chapter 3).

A second wave of institutional control of ethical practices and procedures was started in the 1980s in United States. It was focused on fraud and deception, concerned with violations of the truth-commitment of science, the first set of research ethical norms presented above. This wave has generally consisted in measures introduced to secure and further develop the ethical self-correction capacities of individual researchers and research groups, for instance by developing codes, introducing teaching arrangements, or installing local and national research ethical committees to handle misconduct cases. Such measures on an institutional and national level are not introduced to replace the traditional self-correcting and self-regulating activities of individuals and groups, but to complement and strengthen them.

The reforms came as a consequence of a new understanding of the prevalence of scientific misconduct and questionable research practices. Up to the 1980s it was a widespread assumption that scientific fraud was extremely rare. In 1987 the editor of the prestigious journal *Science* even suggested only one case in a million (Koshland, 1987). During the 1990s it became more common in the United States to claim that misconduct was more widespread than this. Some estimates were based on reported cases that had been investigated by institutions like the Office for Research Integrity (ORI). Such studies indicated that the prevalence was one case in 100 000 researchers. Other studies were based on misleading surveys producing too high estimates, and talk about the tip of the iceberg. With reference to new empirical studies, including anonymous questionnaires where individual scientists informed about their own misconduct, Steneck suggested the "level of occurrence for serious misconduct" was rather one in 100 (2006, p. 58). Several recent studies indicate the same order of magnitude, between 1 and 3% (Fanelli, 2009; Anderson et al., 2013, pp. 232–235). Obviously it is very difficult to give a reliable estimate of this type of phenomenon. But we now have good grounds to claim that scientific misconduct today is not rare. One to three researchers among one hundred having at least once been responsible for scientific fraud is an alarmingly high level.

There are good reasons to assume that the amount of misconduct varies between the different types of fraud. The amount of fabrication of fictitious data, for instance, is in all probability much smaller than the amount of plagiarism. There are probably also considerable variation between disciplines, institutions, and countries. There is still little systematic knowledge about this. In comparison with the United States, the number of empirical studies of this phenomenon is low in Europe. And we have even fewer studies in other regions of the world.

Before World War II the relationships among basic research, politics, and commercial activities, were looser and more indirect than they are today. After World War II we have seen an enormous growth of science, and science has got an increased strategic and commercial relevance. To characterize the development Ziman talks about the emergence of 'post-academic science' (Ziman, 2000, pp. 67–82). The new structures have put the ethos of science under new pressure, and have probably increased the prevalence of scientific dishonesty during the past 30–40 years, although that is difficult or impossible to document.

The traditional ethos of science is an internal and informal system of self-regulation, a set of institutional imperatives

operating at the level of researchers, groups, and networks of individuals. In a recent contribution this institutional culture of self-correction was analyzed and its continuing importance underlined (Anderson et al., 2013, pp. 220–222, 253). And Ziman organizes his book (2000) around the Mertonian norms and insists on the increased importance of research ethics in the 'post-academic' situation (Ziman, 1998). Today this traditional system of self-regulation at the level of individuals and groups has not only to be more explicitly cultivated, taught, and supervised, but also has to be complemented with procedures, positions, and committees on higher levels, such as at the level of organizations, for instance with research integrity *ombud* and ethical committees in universities. Codes and institutions at the national (such as the Norwegian research ethical committees, see www.etikkom.no) and international level (see ESF, 2011; Singapore statement, 2010; Montreal statement, 2013) are also needed. The task of the new systems is to complement, guard, control, and further develop traditional self-regulation in the research communities, not to replace them. A legal–administrative replacement system, for instance, would pervert the inner workings of scientific communities and create more problems than those solved (Kalleberg, 2015). The ethos of science can only function optimally at the field-specific level of working scientists, as an essential and integrated element in their scholarly and scientific work.

Abstract

This contribution analyzes the material, social, and cognitive dimensions of the Scientific Revolution as independent and irreducible dimensions. In discussing the social dimension, the contribution will delineate the impact of the great engineering projects of the Renaissance on the formation of a new social group, dealing both with the practical problems and with the theory of nature. In discussing the material dimension, it will address the intellectual challenges represented by new objects of contemporary technological practices and, in discussing the intellectual dimensions, it will show how mental models of traditional thinking merge with those of practical thinking to form the basis for what eventually will become the conceptual novelties generated by the Scientific Revolution.

The Term 'Scientific Revolution'

The term 'Scientific Revolution' was introduced to denote what has been considered since the nineteenth century as one of the most important discontinuities in the history of European science (H.F. Cohen, 1994; I.B. Cohen, 1985; Lindberg and Westman, 1990). It covered roughly the period between Copernicus and Newton, and led from Aristotelian natural philosophy (*see* Aristotle (384–322 BC)) deriving its dogmatic authority from the Church to the establishment of the classical sciences and their institutions, i.e., the period between 1500 and 1700 (*see* Scientific Disciplines, History of).

This period can be characterized as a period in which a new social group, the 'engineer-scientists,' (consisting of engineers, scientists, inventors, artists, and explorers) emerged and became institutionalized. This group confronted traditional natural philosophy with the challenges of practice and experience, but also engaged in self-contained explanations of natural phenomena, expecting that science is a means to master nature, as Francis Bacon puts it. Among the lasting achievements of the Scientific Revolution were the establishment of heliocentric astronomy, classical mechanics, as well as numerous contributions to optics, chemistry, physiology, and other areas of modern science (for overviews, see Butterfield, 1965; Daston and Park, 2006; Dear, 2001; Dijksterhuis, 1986; Hall, 1954; Rossi, 2001). Many of these achievements became, in fact, the basis for technological breakthroughs. However, these breakthroughs occurred, as a rule, much later than anticipated by the protagonists of the Scientific Revolution. Further, the intellectual breakthroughs responsible for the revolution's lasting impact on the development of science were mainly attained toward its end and only a generation or more after their proclamation by the early pioneers (Damerow et al., 2004).

The Scientific Revolution has become a paradigmatic reference for all approaches to the history and philosophy of science (*see* History of Science). At least since the Enlightenment, it has been conceived as the triumph of the scientific method over the irrationalism of religious beliefs (*see* Science and Religion). Opposition to this view, together with a growing professionalization of historical studies, has opened up the space for other accounts, including attempts – such as that by Pierre Duhem – to deny that the Scientific Revolution actually represented a radical break, claiming instead that it merely constituted an episode within a continuous accumulation of scientific knowledge since the Middle Ages (Duhem, 1996). Furthermore, the traditional emphasis on the role of outstanding protagonists of the Scientific Revolution, such as Bacon, Galileo, and Descartes, and their individual 'discoveries' (see, e.g., Koyré, 1978) has, in recent scholarship, increasingly receded in favor of an analysis of contexts tracing scientific achievements back to cultural, social, and economic conditions (Osler, 2000; Porter and Teich, 1992; Shapin, 1996). The Scientific Revolution, on the other hand, itself provided a model for historical explanations when Thomas Kuhn (*see* Kuhn, Thomas S. (1922–96)) radically challenged traditional historiography with his notion of 'scientific revolution' conceived of as a general structure of knowledge development (Kuhn, 1962).

Historical and Sociological Context

From a sociological perspective, the Scientific Revolution appears as part of a wider social process in which technical knowledge assumed a new role in the organization of European societies (*see* Renaissance; Enlightenment). This process took off in the late Middle Ages and was primarily rooted in the larger cities, which saw an ever more diversified and developed artisanal culture and a growing accumulation of merchandise capital. The cities of early modern Europe thus offered favorable conditions to the rapid growth of technical knowledge and the reflection of this growth in political, philosophical, and religious thinking. Large-scale ventures involving technical expertise, such as projects of military architecture, water regulation, or seafaring expeditions involved types of resources, social mobility, and an outlook on the world available only in urban centers such as Florence, Venice, Paris, and London, which in fact became, long after they had attained an outstanding economic role, also the nuclei of the Scientific Revolution. Historians such as Edgar Zilsel (2000) have considered the early modern engineering projects as a decisive condition for the practical orientation and the empirical knowledge base that distinguish the science of this period from its medieval

[†]Deceased.

antecedents (see Freudenthal and McLaughlin, 2009; Long, 2011; Olschki, 1965; Smith, 2004; Valleriani, 2010).

Beginning in the fifteenth century, ambitious practical ventures (such as the building of the cupola of the Florentine Cathedral, the search for a sea route to India, or the development of a new military technology) increasingly relied on expert knowledge comprising both logistic and technological competencies exceeding those of traditional practitioners and artisans. Such competencies could only be gained on the basis of a broader reflection on the relevant practical and theoretical knowledge resources available. This reflection became the specialty of the new group of engineer-scientists such as Filippo Brunelleschi, Christopher Columbus, Leonardo da Vinci, Niccolo Tartaglia, and Galileo Galilei. While the states of the time (if not actually at war) competed with each other in the pursuit of practical ventures, for example, building projects or seafaring expeditions, the knowledge acquired in such ventures was nevertheless constantly spread among the engineer-scientists employed by them. In the social fabric of the early modern period, engineer-scientists occupied a place similar to that earlier conquered by Renaissance humanists, administrators, and artists (*see* Art History). These practically oriented intellectuals were, as a rule, highly mobile, offering their services to whatever patronage was available. At the same time, they constituted, as a social group, a collective memory, accumulating and transmitting the new knowledge long before appropriate institutions of learning emerged and in spite of the frequent political and military turnovers of the time.

The characteristic features of the engineer-scientists and their work become understandable against the background of their uncertain social status and their dependence on the patronage of courts and city governments (see, e.g., Biagioli, 1993) with rapidly changing power structures. Examples are their incessant engagement with projects for potential future patrons; their usually unrealistic promises regarding the practical benefits of their theories, inventions, or projects; the secrecy with which they treated their discoveries; their frequent involvement in priority struggles; as well as the striving to ennoble their practical knowledge with the claim of creating 'new sciences.'

The social and political ambitions of the engineer-scientists were reflected in their pursuit of a literary culture of technical knowledge, largely emulating the humanist culture of the courts, including their reference to ancient Greek and Roman canons. Their contribution to the literary culture was in turn welcomed by those interested in challenging the transcendent, religious legitimization of the feudal order as an argument for the possibility of an immanent explanation of both the natural and the social world. This affinity, together with the fact that an all-encompassing explanation of the world on the basis of Aristotelian philosophy had been adopted as the official doctrine of the Catholic Church, brought the engineer-scientists almost unavoidably into conflict with its power structures (Feldhay, 1995).

Other developments contributed to turning the growth of technological and scientific knowledge into a force driving profound changes in the established structures of European society. The invention of printing offered a revolutionary new means of dissemination that challenged the exclusiveness of a literary culture based on manuscripts. The new dissemination technique contributed to overcoming the traditional separation between various branches of practical knowledge, confined by a transmission process relying exclusively on participation and oral communication as well as restricted by guild regulations. It also bridged the social gulf between such practical knowledge and the theoretical knowledge transmitted via scholarly texts at universities, monasteries, and courts. As a result, knowledge resources of different provenance were integrated and became widely available. Together with the accumulation of new knowledge in the context of the great practical ventures of the time, this process formed part of a veritable explosion of knowledge, both in the sense of its expansion and of its spreading across traditional social barriers.

In reaction to this knowledge explosion and its growing significance for the functioning of the advanced European societies, new institutions of learning such as the Accademia del Cimento (1657), the Royal Society (1660), and the Académie Royale des Sciences (1666) emerged in the middle of the seventeenth century (*see* Knowledge Society, History of). Traditional institutions, such as those of the Church, on the other hand, had to accommodate to the new situation, as may be illustrated by the prominent involvement of Jesuits in the scientific culture of the time (Wallace, 1991). Parallel to this process of institutionalization, science had, toward the end of the period here under consideration, gradually emancipated itself from the expectation of immediate practical benefits and could increasingly be pursued for its own sake. In summary, as a result of the Scientific Revolution, not only the production and transmission of technological knowledge but also its reflection by scientific theories became an essential factor in the social, economic, and cultural development of European societies. This is the context in which scientists such as Huygens, Leibniz, Hook, Newton, and Wallis traditionally identified with the completion of the Scientific Revolution by the creation of classical terrestrial and celestial mechanics, achieved their celebrated results.

Structures and Achievements

The cognitive, social, and material structures and achievements of the Scientific Revolution have been extensively studied and discussed amid much controversy. Recent scholarship in the context of a cultural history of science has emphasized the possibility of an integrative treatment of these various dimensions. From the point of view of the traditional history of ideas, the Scientific Revolution appears primarily as the renewal of a knowledge development going back to antiquity, as a renaissance of Greek science. In fact, the ancient tradition of mathematical science, and in particular the 'Elements' of Euclid, provided the protagonists of the Scientific Revolution with the canonical model for a mathematical theory, a model which they systematically applied to new areas such as ballistics (Tartaglia), (see Valleriani, 2013) and even ethics (Spinoza). But the ancient tradition also had in stock designs for a theory of nature not based on Aristotelian views which they could hence exploit in their struggle against scholasticism, in particular Platonism and atomism. The ancient tradition finally offered a substantial corpus of knowledge in such domains as geometry, mathematical astronomy, and mechanics, serving as

a point of departure for new scientific endeavors. The perception of their work as a renewal of antique science was typical of the self-image of the protagonists of the Scientific Revolution, who honored each other by such titles as that of a 'new Archimedes.' In short, the characterization of the Scientific Revolution as a renaissance of antique science by historians of ideas such as Koyré is in agreement the claims of contemporary scientists to have accomplished a radical break with Aristotelian scholasticism (Koyré, 1978).

This characterization, however, is in apparent conflict with the results of studies inaugurated by scholars in the tradition of Duhem, pointing to a conceptual continuity between early modern science and its medieval predecessors (and even with contemporary scholasticism), in spite of the anti-Aristotelian polemics (Duhem, 1996). Such studies have provided evidence that the intellectual means available to the engineer-scientists engaged in creating new sciences were essentially still rooted in traditional conceptual frameworks. For instance, the investigations of motion and mechanics by Galileo Galilei and his contemporaries were shaped by such Aristotelian notions as the distinction between natural and violent motion and the assumption that violent motion is caused by a moving force (Damerow et al., 2004; Renn and Damerow, 2012). Studies of medieval natural philosophy have revealed, on the other hand, that the advanced explanations of phenomena such as projectile motion, by which early modern scientists distinguished themselves from Aristotelian natural philosophy, make use of concepts of causation such as that of 'impetus' (or 'impressed force') and techniques for conceptualizing change such as Oresme's doctrine of the 'latitude of forms' that had already been developed by late antique or medieval commentators on Aristotle (Clagett, 1968).

Such contrasting accounts of early modern science appear less incompatible if other dimensions of the development of scientific knowledge are taken into account. For instance, epistemological considerations have suggested that one should differentiate between the claim of Renaissance engineer-scientist to have created a new science or a new scientific method, on the one hand, and the knowledge base they shared with their contemporaries, on the other. Using terminology introduced by Elkana (1988) we can say that their ambitious claim resulted from the 'image of knowledge,' which was determined by their fragile social status. This image is to be distinguished from the shared 'body of knowledge' comprising the antique and medieval heritage which determined what challenges they were able to master. The role of this shared knowledge for the Scientific Revolution has been analyzed not only from the point of view of the history of ideas, but also from the viewpoint of its actual function in the social and material contexts of this revolution. It has thus turned out that the material culture of the Scientific Revolution decisively shaped the way in which the knowledge of antique and medieval science was taken up or newly interpreted.

It has become evident, for instance, that the knowledge resources available to the engineer-scientists, largely structured by traditional conceptual frameworks, were challenged by their application to the new objects of a rapidly expanding range of experience, acquired in the context of the practical ventures in which the engineer-scientists were engaged. While investigations of 'challenging objects' such as the pendulum, the trajectories of artillery, purified metals, the dissected human body, the terrestrial globe, and the planetary system often remained less successful than their protagonists hoped and claimed, they nevertheless triggered elaborations and modifications of these traditional frameworks creating the foundations for the accomplishments of the age of classical science. Columbus searched for the sea route to India, but discovered America. Kepler tried in the Pythagorean tradition to unravel the harmonies of the world but from the harmonies he found only three laws of planetary motion that became the starting point of Newtonian cosmology. Galileo explained ballistics and pendulum motion on the basis of the impetus concept, but in fact he contributed to a new mechanics, which expelled this concept once and for all from science. Harvey defended Aristotle's claim of the primacy of the heart among the organs, but became the founder of an anti-Aristotelian theory, a mechanistic medicine. All these achievements resulted from coping with challenging new objects while relying on essentially traditional intellectual means.

Classical science, often considered an accomplishment of the Scientific Revolution, was actually established for the most part only in the course of the eighteenth century. Even classical mechanics, the pilot and model science of the Scientific Revolution, assumed the formulation familiar from today's physics textbooks only in the aftermath of Newton's pioneering work. The characteristics of classical science, relatively stable theoretical frameworks and generally accepted standards for the production of knowledge serving as the canonical reference for a scientific community, were, in any case, not yet shared by the scientific endeavors of the Scientific Revolution.

The conceptual framework of classical science comprising basic concepts such as inertia, a new methodical canon including the experimental method, and mathematical techniques such as differential calculus, new images of knowledge such as the mechanization of the worldview, and the new institutions of classical science such as the academies, were nevertheless consequences of the achievements of the Scientific Revolution, as a belated result of reflection on its accumulated experience.

Abstract

This article provides an overview of the field of scientometrics, that is, the study of science, technology, and innovation from a quantitative perspective. We cover major historical milestones in the development of this specialism from the 1960s to today and discuss its relationship with the sociology of scientific knowledge, the library and information sciences, and science policy issues such as indicator development. The disciplinary organization of scientometrics is analyzed both conceptually and empirically. A state-of-the-art review of five major research threads is provided.

Introduction

Scientometrics can be defined as the "quantitative study of science, communication in science, and science policy" (Hess, 1997: p. 75). What started as Eugene Garfield's idea of an index to improve information retrieval in the 1960s and resulted in the creation of the *Science Citation Index* (SCI) (Garfield, 1979; Wouters, 1999) was soon recognized as a novel instrument in the empirical study of the sciences (e.g., de Solla Price, 1965; Cole and Cole, 1973). The availability of output indicators (such as databases of publications and patents) complemented ongoing efforts by the Organisation of Economic Cooperation and Development (OECD) in Paris to standardize input statistics of the scientific enterprise (OECD, 1963/1976). Based on these data, the National Science Board of the United States initiated the biannual series of *Science Indicators* in 1972. (The series was renamed into *Science and Engineering Indicators* in 1987 (National Science Board, 2012).)

The new journal *Scientometrics* was launched in 1978 and in that same year leading historians, philosophers of science, and social scientists – among them Robert K. Merton – published an edited volume entitled *Toward a Metric of Science: The Advent of Science Indicators*, in which they reflected on the new perspectives (Elkana et al., 1978). The historian Derek J. de Solla Price published a number of books and articles in the 1960s and 1970s which laid the foundations for the newly emerging field of quantitative science studies (e.g., de Solla Price, 1961, 1963, 1965), culminating in a full-fledged research program (de Solla Price, 1976).

The sociology of science, however, during the 1980s turned increasingly toward microanalysis focusing on the behavior of scientists in laboratories (e.g., Latour and Woolgar, 1979). From this perspective, the quantitative analysis of scientific literature at the macro (e.g., disciplinary) level was not considered a useful tool to explain scientific practices (Edge, 1979). Rather, with its focus on scientific communications – as a unit of analysis potentially different from scientists as authors – scientometrics developed at arm's length from the sociology of science and closer to the library and information sciences. At the same time, the value of scientometric indicators for informing science policies and research management became manifest (Irvine and Martin, 1984).

Under these diverging pressures, the field of science and technology studies increasingly bifurcated during the period 1985–2000 into qualitative 'sociology of scientific knowledge' on the one side, and the quantitative study of scientometrics and science indicators, on the other. Additionally, a third line of research emerged that published articles that use insights from the quantitative study of science and technology for evaluation and policy purposes. Such research appeared in journals such as *Research Policy*, *Research Evaluation*, and *Technology Analysis & Strategic Management* (Leydesdorff and Van den Besselaar, 1997).

During the 2000s, attention to evaluation and ranking was further enhanced after the publication of the first Academic Ranking of World Universities (ARWU) of the Shanghai Jiao Tong University in 2004 (Shin et al., 2011). The use of impact factors of journals for evaluative purposes has in the meantime pervaded the academic environment, even to the level of individual tenure decisions, which increasingly are being based on quantitative measures of publications and citations. Another popular indicator, the *h*-index (Hirsch, 2005), provides a simple impact metric for individual authors that can readily be used in online searching, for example, with Google Scholar, but is also incorporated in the major citation databases such as the Web-of-Science and Scopus. Computer programs (e.g., *Publish or Perish* at http://www.harzing.com/pop.htm) can freely be downloaded from the Internet and allow for measuring numbers of publications, citations, *h*-index, *g*-index (Egghe, 2006), etc., at the level of individuals, journals, and institutions without much prior knowledge of the scientometrics involved. In the meantime, the production and improvement of these indicators has become organized in university departments, spin-offs, and relevant companies such as Elsevier and Thomson-Reuters.

The increased access to large datasets through the Internet led to the development of the network sciences as part of computing and applied physics during the first decade of this century (e.g., Newman, 2010). A number of these studies used coauthorship and citation data for modeling the network dynamics. Although these efforts to model the evolution of the sciences statistically (e.g., Scharnhorst et al., 2012) often do not aim at contributing to social–scientific understanding and theorizing, the new methods (e.g., visualization techniques) developed by these researchers are partly derived

from and have also been adopted by scientometricians. Such interdisciplinary exchanges make scientometrics an active research specialty that in the 2000s has been experiencing a spectacular growth in its literature. More recently, the specialty has come to increasingly be considered as a 'research front' in terms of the turnover of the referencing patterns (Milojević and Leydesdorff, 2013; Wouters and Leydesdorff, 1994).

The Disciplinary Organization of 'Scientometrics'

Unlike the behavioral sciences and mainstream philosophy of science, scientometrics focuses on texts (documents) as empirical units of analysis. Figure 1 schematizes the relations with other disciplinary perspectives in science studies. Texts cannot be reduced to their authors – texts can, for example, be coauthored – nor can theories be reduced to the documents in which they are published. However, a measure in one dimension can be used as a proxy or indicator for the other given a research design.

As against texts or people, contents and theorizing remain latent and thus have to be theorized and hypothesized. Using factor analysis, however, one can reorganize data so that, for example, latent journal structures can be derived from the aggregation of citation linkages among journals. In Figure 2, we have applied techniques from network analysis to distinguish four communities in the citation networks among 32 journals that were cited by authors in *Scientometrics* during 2010. (All journals are included which contributed more than 1% to the total number of references in the journal *Scientometrics* during this year (2010).)

Figure 2 shows that *Scientometrics* as a journal has mainly been situated within the information sciences. The *Journal of the American Society for Information Science and Technology* (JASIST) has become a major publication outlet for scholars in this field in addition to the more specialized journals (such as *Journal of Informetrics* that was newly founded in 2007). However, the journal *Scientometrics* is the core journal in this field that interfaces with *Social Studies of Science*; a journal that mainly publishes qualitative science studies, and with general science journals (such as *Science* and *Nature*) and a number of journals that can be considered as part of technology and innovation studies (e.g., *R&D Management* and *Research Policy*). The relation with social network analysis and organization studies is more remote, but also visible.

Figure 1 Three main dimensions in the dynamics of the sciences. Adapted from Leydesdorff, L., 1995. The Challenge of Scientometrics: The Development, Measurement, and Self-organization of Scientific Communications. DSWO Press, Leiden University, Leiden.

At the lower-left side of Figure 2, one also can see strong links to a group of major multidisciplinary journals (*Nature*, *Science*, *Proceedings of the National Academy of Science of the USA (PNAS)*) and physics journals (*Physical Review E* and *Physica A*). These journals mostly publish the research of network science researchers – physicists and applied mathematicians – who discovered bibliographic databases as resources and study objects at around the turn of the century. These developments in physics and mathematical statistics have become part of the relevant environments for scientometric research, but the relevant journals are positioned very differently from journals such as *Social Networks* and *Administrative Science Quarterly* (at the top-right side of Figure 2). In other words, scientometric research nowadays is at the crossroads among the social sciences, information science, and advanced computing with its efforts to capture patterns in 'big data.'

Major Research Issues

The Measurement of Impact

The modern citation emerged in scientific literature – notably in chemistry – at the end of the nineteenth century as a standardized format (Bazerman, 1988; Leydesdorff and Wouters, 1999: p. 175). Citation indexing was organized during the 1960s (Garfield, 1979; Wouters, 1999; cf Cronin, 1984). With the advent of Google Scholar and Scopus as alternative citation indexes in 2004, citation analysis and rankings have become increasingly paradigmatic in research management and science policies. Discussions about the meaning of citations and the derived indicators tend to drive the scientometric enterprise.

For several decades, citation impact has been measured as the average number of citations per publication (c/p), and the impact factor (*IF*) was defined as a 2-year moving average at the level of journals. Citation distributions, however, are right-skewed because of cumulative advantages (de Solla Price, 1965, 1976) or, in other words, the 'Matthew Effect' in science (Merton, 1968) – the tendency for citation-rich authors and publications to draw further citations, in part *because* they are heavily cited. Therefore, the use of central tendency statistics (such as the arithmetic mean) is ill advised.

In addition to violating statistical assumptions, the use of the mean can affect the calculated impact when applied to different levels of aggregation by placing the number of publications in the denominator. For example, a Principal Investigator (PI) may lose average impact when his/her publications with junior staff are included in the set to be evaluated. However, a research group has more cumulative impact than its individual PI. Obviously, one needs a measure that can be aggregated, but after a normalization of the raw citation scores for differences among fields of science.

In 2010 and 2011, a scholarly debate (e.g., Gingras and Larivière, 2011) led gradually to the acceptance in measuring

Figure 2 Map of 32 journals based on citing documents published in *Scientometrics* during 2010; Pajek used for the visualization; cosine >0.1; four communities detected with modularity $Q = 0.506$.

the impact of using percentiles and nonparametric statistics that accord with the skew in the distributions. The *Science and Engineering Indicators* (National Science Board, 2012), for example, uses six classes: the top-1%, top-5%, top-10%, top-25%, top-50%, and bottom-50%, but these measures can be further developed into appropriate statistics. Percentile ranks remain – like numbers of citations but now normalized – attributes at the article level and can be aggregated at different levels: institutions, nations, or even œ*uvres* of individual scholars. Statistical significance can be specified and error indicated, both in comparisons and with reference to expectations. The SCImago Institutions Rankings 2011 and Leiden Rankings 2011 of top universities, for example, both use the top-10% as an *excellence* indicator for which one can test for differences statistically (Bornmann et al., 2012).

Statistics based on normalization of the citation curves instead of averaging may lead to very different results. Using 2009 data, for example, Leydesdorff and Bornmann (2011) showed that PNAS could thus be attributed an impact that was significantly higher than *Science* or *Nature*, although, according to the usual measure, the latter journals had an impact factor that was three times higher. In brief, the new (nonparametric) indicators correlate more strongly with citations and publications than impact factors or other measures based on central tendency statistics.

Hirsch's (2005) *h*-index became another popular impact metric for capturing both the productivity and impact of an individual author. The index itself is crude, but there have been attempts to improve it. For example, Egghe proposed a *g*-index (2006) that increases the sensitivity of *h*-index values to highly cited papers. These indexes can be used for ranking scholars within a single discipline, because publication and citation behavior varies across disciplines. Recently, there have been proposals to create so-called 'universal' indexes, that is, indexes that can be used to evaluate and rank scientists across disciplines (e.g., Radicchi et al., 2008).

The Delineation of a Reference Set

A largely unresolved problem in scientometrics has been the delineation of reference sets for measuring the impact of journals or institutional units. Reference sets are a condition for appropriate normalization. The results of a scientometric evaluation can be highly sensitive to the attribution of papers to particular disciplines or specialties, and to the way specialties and (inter)disciplines are delineated. This makes it very difficult to delineate reference sets for universities that include multidisciplinary units (Rafols et al., 2012).

Following up on Moed (2010), Leydesdorff and Opthof (2010) proposed to use the citing papers as reference sets and to fractionate the citation credit in accordance with the length of the reference lists. This procedure takes into account that papers can address a variety of audiences with different citation practices. Using all publications in 2005 with Tsinghua University in Beijing as the institutional address, for example, Zhou and Leydesdorff (2011) showed that the department of Chinese Language and Literature would be

upgraded from the 19th to the 2nd position in the ranking among departments of this university if the citation scores were counted fractionally. Although fractionation moderates the effects of differences among disciplines, it does not enable articles that are not cited to be assessed.

In general, the problem remains that the citation matrices can be decomposed into (disciplinary) groupings to a variable extent. A single threshold therefore cannot remove the fuzziness that results from variations among fields of science. At the microlevel, a scientometrics researcher may carefully design appropriate sets of documents for representing relevant environments in considerable detail (**Figure 2** is a case in point). However, the specificity in each subset may make it difficult to aggregate sets from which more general conclusions can be drawn. The exception may be the rule in some sciences more than in others.

Theories of Citation

In line with different traditions in the sociology of science, it is possible to distinguish a normative from a constructivist theory of citations and other scientometric artifacts. Following Merton's (1942) set of norms – communalism, universalism, disinterestedness, and organized skepticism – one can argue that citations are a manifestation of influence and can therefore be considered as a currency for paying tribute in science (Zuckerman, 1987). This normative model has been countered by discourse-analytic arguments that emphasize the rhetorical construction of references in texts (Cozzens, 1989; Gilbert, 1977).

Fujigaki (1998) provided an interpretation of referencing in scientific papers as an important part of the self-organizing system in scientific fields: by providing citations, authors select those elements from the previously existing knowledge base which have to be retained for further development in a next round. Leydesdorff (1998) added that texts and authors constitute layered networks in which citations are expected to have different meanings. The system in the present can thus move forward referencing both the social and intellectual organization of science, while potentially following trajectories based on mutual adjustments between selections in these dimensions. Trajectories, however, can also be metastabilized and then globalized into regimes or paradigms. An evolutionary model of science is thus envisaged that is open for simulation and empirical research (Scharnhorst et al., 2012).

Mapping Science

Following Rip (1988: p. 254), a map of science can be defined as "the visualization of the topology of relationships between elements or aspects of science." Mapping of science can be useful for three purposes: retrieving information, understanding the dynamics of science, and informing science policy decisions about the allocation of resources (i.e., funding) and rewards. Scientometric analysis focuses on revealing the internal structure of intellectual domains, that is, mapping the components of disciplines, fields, or specialties on the basis of evidence from the literature under study. This can be achieved by mapping subject terms, documents, authors' *œuvres*, or journals. The basic data are cooccurrence counts.

Callon et al. (1986) argued that the sciences develop as heterogenous networks. In addition to heterogeneity across institutional domains (university, industry, government), organized knowledge can flexibly be codified in terms of mixtures of cited references and word usages. Words are more volatile than citations. Coauthorship relations, however, are not sufficiently informative of intellectual content for a semantic map; social network analysis has to be combined with semantic maps in order to generate rich representations. A longer-term challenge for this agenda is the animation of the informed networks over time, preferentially with specification of the statistical error involved. Advances in visualization and animation can further inform our understanding of the role of citations, title words, keywords, author names, etc., in evolving networks of scientific communication.

Policy and Management Contexts

Scientometricians also construct indicators that can be used in policy and management contexts. In these contexts, utility is sometimes more important than validity. For example, the use of impact factors to evaluate faculty members involves a combination of analyses at different levels of aggregation, and eventual applications to relatively small sets. Science maps and overlays to geographical maps can function heuristically at the aggregate level, but testing for significance requires sufficiently large sets.

The use of scientometric indicators for strategic choices at low levels of aggregation, such as 'picking the winners' (Irvine and Martin, 1984) in competitions for funding, is sensitive to the problem of relatively small sets, the operationalization of quality (e.g., the normalization of indicators across specialties and disciplines), and also the intrinsic problem of selecting the 'excellent' candidates for funding from an already preselected set of fundable proposals. Bornmann et al. (2010) showed in a number of cases that 'best rejected' proposers, when matched as pairs with grantees, scored higher on performance and impact indicators at a statistically significant level. The peer review process may introduce normative bias without intending to do so, in a process of selecting 'excellent' proposals from a pool of 'good' proposals. Scientometric metaevaluation may help with improving the selection process by enhancing awareness that it is not always possible to distinguish 'excellent' from 'good' research despite pressures for doing so for policy reasons.

Conclusions and Further Perspectives

The scientometric perspective adds a quantitative focus on texts and communication to the interdisciplinarity of science and technology studies. The philosophical distinction between 'context of discovery' and 'context of justification' (Popper, [1935]1959) was first overcome in empirical science studies that focus on interactions in which the social and cognitive organization of the sciences are continuously and actively reconstructed and recombined. However, this social and

intellectual process is textually mediated because texts can 'travel' more easily than scholars do, and thus the global dimension of paradigmatically structured horizons of meaning can be instantiated in relation to locally generated novelty. At the level of texts (e.g., manuscripts), one is able to recombine references to both local agency (author names, institutional addresses) and cognitive organizers such as title words and journal names. Furthermore, the content of manuscripts is validated (by peer review in contexts of justification) and thereupon the texts are admitted to the archive of published, and thus authenticated, scholarship on which future work can be built. These processes can be traced because they are documented.

The field of scientometrics has also expanded to different types of documents and other domains. For example, a similar process is working in the technological domain, but with a different dynamics (Dosi, 1982). Like manuscripts, patent applications contain knowledge claims that refer to 'prior art.' However, the functions and therefore the institutional incentives are different: patents are meant to protect intellectual property, whereas the public sciences are also based on the principle of gift giving (Merton, 1973). As publications, patents can be searched on the Internet, and the data can then be reorganized in terms of lines of intellectual heritage using citations, inventor names, institutional addresses, etc. Overlays on Google Maps, for example, allow for studying the geographic diffusion of new technologies based on sets and series of patented inventions.

Texts span networks of relations among authors, inventors, cognitions, institutional addresses, journals, etc. These networks contain both social (including economic) and cognitive relations. The cognitive dynamics are different from the social dynamics in that meaning is reflexively provided (that is, from the perspective of hindsight), while the historical networks develop with the time arrow. Thus, forward and backward loops are intertwined. Whereas the forward arrow necessarily generates Shannon-type information – uncertainty, variation – the backward loops can selectively reduce uncertainty by providing meanings to the events. Using the theory and computation of anticipatory systems (Dubois, 1998), the two operations can be distinguished as reconstructive incursion versus historical recursion.

In summary, the modeling of knowledge exchanges in scientific discourses cannot be reduced to the exchanges of information in coauthorship, coword, or citation relations. Models as entertained in the sciences enable researchers both to provide meaning to possible future states and to specify uncertainty. The measurement of the communication/sharing of meaning among frames of reference – for example, in university–industry–government relations – is very much on the research agenda of scientometrics (e.g., Leydesdorff and Ivanova, in press), but still a step away from how meaningful communication can further be codified in scientific discourses.

Models also serve to communicate possible future states. A construction of future states from a knowledge-based perspective can be modeled as hyperincursion. The modelers/scientists thus become carriers who are differently positioned in terms of their reflexive and communicative competencies; for example, as scientific explorers and/or appliers of engineering knowledge. The (re)constructions and their interactions update and reinforce the knowledge bases of the evolving societies and their economies. Authors in scientometrics are able to contribute to the study of science, technology, and innovation from a quantitative perspective by modeling and measuring these developments.

Screening and Selection

Joseph L Gastwirth, George Washington University, Washington, DC, USA

This article is reproduced from the previous edition, volume 20, pp. 13755–13760, © 2001, Elsevier Ltd, with an updated Bibliography section supplied by the Editor.

Abstract

Procedures for classifying individuals as possessing a characteristic or trait are used to make decisions concerning university admissions and employee selection, auditing tax returns, health status or the need for more extensive diagnostic procedures, and the veracity of accused criminals or job applicants for security sensitive jobs. The statistical concepts underlying these screening methods and their proper interpretation in a variety of fields are described. The role of the prevalence of the trait in the population screened is stressed. In many applications the true status of an individual cannot be determined perfectly so special studies are needed to estimate the accuracy of screening tests. In addition to selecting individuals for a position or for special treatment, results of screening tests can be used to estimate the prevalence of a trait in a population. For some purposes, e.g., screening blood donations for HIV/AIDS, a test that is not accurate enough to classify an individual can still be very useful in protecting the public.

Introduction

In order to assist in selecting individuals possessing either desirable traits such as an aptitude for higher education or skills needed for a job or undesirable ones such as having an infection, illness, or a propensity to lie, screening tests are used as a first step. A more rigorous selection device, e.g., diagnostic test or detailed interview is then used for the final classification. For some purposes, such as screening blood donations for a rare infection, the units classified as positive are not donated but further tests on donors may not be given as most will not be infected. Similarly, for estimating the prevalence of a trait in a population, the screening data may suffice provided an appropriate estimator that incorporates the error rates of the test is used (Hilden, 1979; Gastwirth, 1987; Rahme and Joseph, 1998). This article describes the measures of accuracy used to evaluate and compare screening tests and issues arising in the interpretation of the results. The importance of the prevalence of the trait on the population screened and the relative costs of the two types of misclassification are discussed. Methods for estimating the accuracy rates of screening tests are briefly described and the need to incorporate them in estimates of prevalence is illustrated.

Basic Concepts

The purpose of a screening test is to determine whether a person or object is a member of a particular class, C or its complement, $C-$. The test result indicating that the person is in C will be denoted by S and a result indicating nonmembership by $S-$. The *accuracy* of a test is described by two probabilities:

$$\eta = P[S|C]$$

being the probability that someone in C is correctly classified, or the sensitivity of the test; and

$$\theta = P[S-|C-]$$

being the probability that someone not in C is correctly classified, or the specificity of the test. Given the prevalence, $\pi = \mathrm{P}(C)$, of the trait in the population screened, from Bayes' theorem it follows that the predictive value of a positive test (PVP) is

$$P[C|S] = \pi\eta/[\pi\eta + 1 - \pi)(1 - \theta)].{}_X$$

Similarly, the predictive value of a negative test is

$$P[C-|S-] = (1-\pi)\theta/[(1-\pi)\theta + \pi(1-\eta)].$$

In the first two sections, we will assume that the accuracy rates and the prevalence are known. When they are estimated from data, appropriate sampling errors for them and the PVP are given in Gastwirth (1987).

For illustration, consider an early test for HIV, having a sensitivity of 0.98 and a specificity of 0.93, applied in two populations. The first has a very low prevalence, 1.0×10^{-3}, of the infection while the second has a prevalence of 0.25. From eqn [1], the PVP in the first population equals 0.0138, i.e., only about one-and-one-half percent of individuals classified as infected would actually be so. Nearly 99% would be false positives. Notice that if the fraction of positives, expected to be 0.0797, in the screened data were used to estimate prevalence, a severe overestimate would result. Adjusting for the error rates yields an accurate estimate. In the higher prevalence group, the PVP is 0.8235, indicating that the test could be useful in identifying individuals. Currently used tests have accuracy rates greater than 0.99, but even these still have a PVP less than 0.5 when applied to a low prevalence population. A comprehensive discussion is given in Brookmeyer and Gail (1994).

The role of the prevalence, also called the base rate, of the trait in the screened population and how well people understand its effect has been the subject of substantial research, recently reviewed by Koehler (1996). An interesting consequence is that when steps are taken to reduce the prevalence of the trait prior to screening, the PVP declines and the fraction of false-positives increases. Thus, when high-risk donors are encouraged to defer or when background checks eliminate a sizable fraction of unsuitable applicants prior to their being subjected to polygraph testing the fraction of classified positives who are truly positive is small.

In many applications screening tests yield data that are ordinal or essentially continuous, e.g., scores on psychological tests or the concentration of HIV antibodies. Any value, t, can be used as a cut-off point to delineate between individuals with the trait and 'normal.' Each t generates a corresponding sensitivity and specificity for the test and the user must then incorporate the relative costs of the two different errors and the likely prevalence of the trait in the population being screened to select the cut off. The receiver operating characteristic (ROC) curve displays the trade-off between the sensitivity and specificity defined by various choices of t and also yields a method for comparing two or more screening tests.

To define the ROC curve, assume that the distribution of the measured variable (test score or physical quantity) is $F(x)$ for the 'normal' members of the population but is $G(x)$ for those with the trait. The corresponding density functions are $f(x)$ and $g(x)$ respectively and $g(x)$ will be shifted (to the right (left) if large (small) scores indicate the trait) of $f(x)$ for a good screening test. Often one fixes the probability ($\alpha = 1 - \gamma\theta$ or one minus the specificity) of classifying a person without the characteristic as having it at a small value. Then t is determined from the equation $F(t) = 1 - \theta$. The sensitivity, η, of the test is $1 - G(t)$. The ROC curve plots η against $1 - \theta$. A perfect test would have $\eta = 1$ so the closer the ROC is to the upper left corner in **Figure 1**, the better the screening test. In **Figure 1** we assume f is a normal density with mean 0 and variance 1 while g_1 is normal with mean 1 and the same variance. For comparison we also graphed the ROC for a second test, which has a density g_2 with mean 2 and variance 1. Notice that the ROC curve for the second test is closer to the left corner (0,1) than that of the first test.

A summary measure (Campbell, 1994), which is useful in comparing two screening tests is the area, A, under the ROC.

Figure 1 The ROC curves for screening tests 1 and 2. The solid line is the curve when the diseased group has mean 1 and the dashed curve is for the second group with mean 2.

The closer A is to its maximum value of 1.0, the better the test is. In **Figure 1**, the areas under the ROC curves for the two tests are 0.761 and 0.922, respectively. Thus, the areas reflect the fact that the ROC curve for the second test is closer to what a 'perfect' test would be. This area equals the probability a randomly chosen individual will have a higher score on the screening test than a normal one. This probability is the expected value of the Mann–Whitney form of the Wilcoxon test for comparing two distributions and methods for estimating it are in standard nonparametric statistics texts.

Nonparametric methods for estimating the entire ROC curve are given by Wieand et al. (1989) and Hilgers (1991) obtained distribution-free confidence bounds for it. Campbell (1994) uses the confidence bounds on F and G to construct a joint confidence interval for the sensitivity and one minus the specificity in addition to proposing alternative confidence bounds for the ROC itself. Hseih and Turnbull (1996) determine the value of t that maximizes the sum of sensitivity and specificity. Their approach can be extended to maximizing weighted average of the two accuracy rates, suggested by Gail and Green (1976). Wieand et al. (1989) also developed related statistics focusing on the portion of the ROC lying above a region, α_1 and α_2 so the analysis can be confined to values of specificity that are practically useful. Greenhouse and Mantel (1950) determine the sample sizes needed to test whether both the specificity and sensitivity of a test exceed prespecified values.

The area A under the ROC can also be estimated using parametric distributions for the densities f and g. References to this literature and an alternative approach using smoothed histograms to estimate the densities is developed in Zou et al. (1997). They also consider estimating the partial area over the important region determined by two appropriate small values of α.

The tests used to select employees need to be reliable and valid. Reliability means that replicate values are consistent while validity means that the test measures what it should, e.g., successful academic performance. Validity is often assessed by the correlation between the test score (X) and subsequent performance (Y). Often X and Y can be regarded as jointly normal random variables, especially as monotone transformations of the raw scores can be used in place of them. If a passing score on the screening or preemployment test is defined as $X \ngeq t$ and successful performance is defined as $Y \ngeq d$, then the sensitivity of the test is $P[X > t|Y > d]$, the specificity is $P[XY < d]$, and the prevalence of the trait is $P[Y > d]$ in the population of potential applicants. Hence, the aptitude and related tests can be viewed from the general screening test paradigm.

When the test and performance scores are scaled to have a standard bivariate normal distribution, both the sensitivity and specificity increase with the correlation, ρ. For example, suppose one desired to obtain employees in the upper half of the performance distribution and used a cut-off score, t, of one-standard deviation above the mean on the test (X). When $\rho = 0.3$, the sensitivity is 0.217 while the specificity is 0.899. If $\rho = 0.5$, the sensitivity is 0.255 and the specificity is 0.937. The use of a high cut-off score eliminates the less able applicants but also disqualifies a majority of applicants who are in the upper half of the performance distribution. Reducing the cut-off score to one-half a standard deviation above the average raises the

sensitivities to 0.394 and 0.454 for the two values of ρ but lowers the corresponding specificities to 0.777 and 0.837. This tradeoff is a general phenomenon as seen in the ROC curves.

The Importance of the Context in Interpreting the Results of Screening Tests

In medical and psychological applications, an individual who tests positive for a disease or condition on a screening test will be given a more accurate confirmatory test or intensive interview. The cost of a 'false positive' screening result on a medical examination is often considered very small relative to a 'false negative,' which could lead to the failure of suitable treatment to be given in a timely fashion. A false positive result presumably would be identified in a subsequent more detailed examination. Similarly, when government agencies give employees in safety or security sensitive jobs a polygraph test, the loss of potentially productive employee due to a false positive was deemed much less than the risk of hiring an employee who would might be a risk to the public or a security risk.

One can formalize the issue by including the costs of various errors and the prevalence, π, of the trait in the population being screened in determining the cut-off value of the screening test. Then the expected cost, which weights the probability of each type of error by its cost is given by

$$w\alpha(1-\pi)+(1-w)\pi G(t).$$

Here the relative costs of a false positive (negative) are w and $1-w$, respectively and as before $t=F^{-1}(1-\alpha)$. The choice of cut-off value, t_0, minimizing the expected cost satisfies:

$$\frac{g(t)}{f(t)}=\frac{w(1-\pi)}{(1-w)\pi} \qquad [1]$$

Whenever the ratio, g:f, of the density functions is a monotone function the previous equation yields an optimum cut-off point, t_0, which depends on the costs and prevalence of the trait. Note that for any value of π, the greater the cost of a false positive, the larger will be the optimum value, t_0. This reflects the fact that the specificity needs to be high in order to keep the false positive rate low.

Although the relative costs of the two types of error are not always easy to obtain and the prevalence may only be approximately known, eqn [1] may aid in choosing the critical value. In practice, one should also assess the effect slight changes in the costs and assumed prevalence have on the choice of the cut-off value.

The choice of t that satisfies condition [1] may not be optimal if one desires to estimate the prevalence of the trait in a population rather than classifying individuals. Yanagawa and Tokudome (1990) determine t when the objective is to minimize the relative absolute error of the estimator of prevalence on the basis of the screening test results.

The HIV/AIDS epidemic raised questions about the standard assumptions about the relative costs of the two types of error. A 'false positive' classification would not only mean that a well individual would worry until the results of the confirmatory test were completed, they also might have social and economic consequences if friends or their employer learned of the result.

Similar problems arise in screening blood donors and in studies concerning the association of genetic markers and serious diseases. Recall that the vast majority of donors or volunteers for genetic studies are doing a public service and are being screened to protect others or advance knowledge. If a donation tests positive, clearly it should not be used for transfusion. Should a screened-positive donor be informed of their status? Because the prevalence of infected donors is very small, the PVP is quite low so that most of the donors screened positive are 'false.' Thus, blood banks typically do not inform them and rely on approaches to encourage donors from high-risk groups to exclude themselves from the donor pool (Nusbacher et al., 1986). Similarly, in a study (Hartge et al., 1999) of the prevalence of mutations in two genes that have been linked to cancer the study participants were not notified of their results.

The screening test paradigm is useful in evaluating tests used to select employees. The utility of a test depends on the costs associated with administering the test and the costs associated with the two types of error. Traditionally, employers focused on the costs of a false positive, hiring an employee who does not perform well, such as termination costs, and the possible loss of customers. The costs of a false negative are more difficult to estimate.

The civil-rights law, which was designed to open job opportunities to minorities, emphasized the importance of using appropriate tests, i.e., tests that selected better workers. Employers need to check whether the tests or job requirements (e.g., possession of a high school diploma) have a disparate impact upon a legally protected group. When they exclude a significantly greater fraction of minority members than majority ones, the employer needs to validate it, i.e., show it is predictive of the job performance. Arvey (1979) and Paetzold and Willborn (1994) discuss these issues.

Estimating the Accuracy of the Screening Tests

So far, we have assumed that we can estimate the accuracy of the screening tests on samples from two populations where the true status of the individuals is known with certainty. In practice, this is often not the case and can lead to biased estimates of the sensitivity and specificity of a screening test, as some of the individuals believed to be normal have the trait, and vice versa.

If one has samples from only one population to which to apply both the screening and confirmatory test, then one cannot estimate the accuracy rates. The data would be organized into a 2×2 table, with four cells, only three of which are independent. There are five parameters, however, the two accuracy rates of the two tests plus the prevalence of the trait in the population. In some situations, the prevalence of the trait may vary among subpopulations. If one can find two such subpopulations and if the accuracy rates of both tests are the same in both of those sub-populations, then one has two 2×2 tables with six independent cells, with which to estimate six parameters. Then estimation can then be carried out (Hui and Walter, 1980).

This approach assumes that the two tests are conditionally independent given the true status of the individual. When this assumption is not satisfied, Vacek (1985) showed that the

estimates of sensitivity and specificity of the tests are biased. This topic is an active area of research, recently reviewed by Hui and Zhou (1998). A variety of latent-class models have been developed that relax the assumption of conditional independence (see Faraone and Tsuang, 1994; Yang and Becker, 1997 and the literature they cite).

Applications and Future Concerns

Historically screening tests were used to identify individuals with a disease or trait, e.g., as a first stage in diagnosing medical or psychological conditions or select students or employees. They are being increasingly used, often in conjunction with a second, confirmatory test, in prevalence surveys for public health planning. The techniques developed are often applicable, with suitable modifications, to social science surveys.

Some examples of prevalence surveys illustrate their utility. Katz et al. (1995) compared two instruments for determining the presence of psychiatric disorders in part to assess the needs for psychiatric care in the community and the available services. They found that increasing the original cut-off score yielded higher specificity without a substantial loss of sensitivity. Similar studies were carried out in Holland by Hodiamont et al. (1987) who found a lower prevalence (7.5%) than the 16% estimate in York. The two studies, however, used different classification systems illustrating that one needs to carefully examine the methodology underlying various surveys before making international comparisons. Gupta et al. (1997) used several criteria based on the results of an EKG and an individual's medical history to estimate the prevalence of heart disease in India.

Often one has prior knowledge of the prevalence of a trait in a population, especially if one is screening similar populations on a regular basis, as would be employers, medical plans, or blood centers. Bayesian methods incorporate this background information and can yield more accurate estimates (see Geisser, 1993; Johnson et al., 2001). A cost-effective approach is to use an inexpensive screen at a first stage and retest the positives with a more definitive test. Bayesian methodology for such studies was developed by Erkanli et al. (1997).

The problem of misclassification arises often in questionnaire surveys. Laurikka et al. (1995) estimated the sensitivity and specificity of self-reporting of varicose veins. While both measures were greater than 0.90, the specificity was lower (0.83) for individuals with a family history than those with negative histories. Sorenson (1998) observed that often self-reports are accepted as true and found that the potential misclassification could lead to noticeable (10%) errors in estimated mortality rates. The distortion that misclassification errors can have on estimates of low prevalence traits because of the high fraction of false positive classifications was illustrated in the earlier discussion of screening tests for HIV/AIDS. Hemenway (1997) applies these concepts to demonstrate that surveys typically overestimate rare events, in particular the self-defense uses of guns. Thus it is essential to incorporate the accuracy rates into the prevalence estimate (Hilden, 1979; Gastwirth, 1987; Rahme and Joseph, 1998).

Sinclair and Gastwirth (1994) utilized the Hui-Walter paradigm to assess the accuracy of both the original and reinterview (by supervisors) classifications in labor force surveys. In its evaluation, the Census Bureau assumes that the reinterview data are correct; however, those authors found that both interviews had similar accuracy rates. In situations where one can obtain three or more classifications, all the parameters are identifiable (Walter and Irwig, 1988). Gastwirth and Sinclair (1998) utilized this feature of the screening test approach to suggest an alternative design for judge–jury agreement studies that had another expert, e.g., law professor or retired judge, assess the evidence.

Conclusion

Many selection or classification problems can be viewed from the screening test paradigm. The context of the application determines the relative costs of a misclassification or erroneous identification. In criminal trials, society has decided that the cost of an erroneous conviction far outweighs the cost of an erroneous acquittal. While, in testing job applicants, the cost of not hiring a competent worker is not as serious. The two types of error vary with the threshold or cut-off value and the accuracy rates corresponding to these choices is summarized by the ROC curve.

There is a burgeoning literature in this area as researchers are incorporating relevant covariates, e.g., prior health status or educational background into the classification procedures. Recent issues of *Biometrics and Multivariate Behavioral Research*, *Psychometrika* and *Applied Psychological Measurement* as well as the medical journals cited in the article contain a variety of articles presenting new techniques and applications of them to the problems discussed.

Abstract

The economics of search study the implications of frictions for individual behavior and market performance, due usually to imperfect information about exchange possibilities. This article reviews labor-market research in this area. Individuals search for a job offer by choosing a reservation wage and accepting jobs that pay above that wage. Firms create jobs to maximize profit. The probability of realizing a match is derived from an aggregate matching function that gives the number of jobs formed in terms of the search efforts of firms and workers. Because of monopoly rents implied by frictions, wages are determined either by bargaining or by take-it-or-leave- it offers posted by firms. Bargaining models share the surplus and give rise to a single wage for homogeneous labor that in general does not allocate jobs efficiently. Wage posting can give rise to a single wage equal to the worker's reservation wage if the worker can only observe one wage offer at a time, or to the efficient allocation if posted wages can be observed but there are job queues, or to a distribution of wage offers if employed workers can sample more than one firm at a time. Job destruction is due either to job-specific shocks or to technological obsolescence.

The economics of search study the implications of market frictions for economic behavior and market performance. 'Frictions' in this context include anything that interferes with the smooth and instantaneous exchange of goods and services. The most commonly studied problems arise from imperfect information about the location of buyers and sellers, their prices, and the quality of the goods and services that they trade. The key implication of these frictions is that individuals are prepared to spend time and other resources on exchange; they *search* before buying or selling. The labor market has attracted most theoretical and empirical interest in this area of research, because of the heterogeneities that characterize it and the existence of good data on flows of workers and jobs between activity and inactivity, which can be used to test its propositions.

Historical Background

The first formal model of individual behavior, due to Stigler (1961), was in the context of a goods market: choosing the optimal number of sellers to search before buying at the lowest price. Stigler's rule, known as a fixed-sample rule, was abandoned in favor of sequential stopping rules: choosing the optimal reservation price and buying at the first store encountered which sells at or below the reservation price (see McCall, 1970, for an early influential paper).

The first big momentum to research in the economics of search came with the publication of Phelps et al. (1970), which showed that search theory could be used to analyze the natural rate of unemployment and the inflation-unemployment trade off, the central research questions of macroeconomics at that time. Although interest in the inflation-unemployment trade-off has since waned, interest in search theory as a tool to analyze transitions in the labor market and equilibrium unemployment has increased. The momentum in this direction came in the 1980s, when contributions by Diamond (1982), Mortensen (1982), and Pissarides (1985) showed that search theory could be used to construct equilibrium models of the labor market with more accurate predictions than the traditional neoclassical model (see Pissarides, 2000; Mortensen and Pissarides, 1999a,b, for reviews). The appearance of comprehensive data on job and worker flows, which can be studied with the tools of search theory, also contributed to interest in this direction (see Leonard, 1987; Dunne et al., 1989; Davis et al., 1996; Blanchard and Diamond, 1989). This article reviews major developments since the mid-1980s, with explicit reference to labor markets.

Job Search

An individual has one unit of labor to sell to firms, which create jobs. The valuation of labor takes place under the assumptions that agents have infinite horizons and discount future income flows at the constant rate r, they know the future path of prices and wages and the stochastic processes that govern the arrival of trading partners, and they maximize the present discounted value of expected incomes. Let U_t be the expected present discounted value of a unit of labor before trade at time t (the 'value' of an unemployed worker) and W_t the expected value of an employed worker. During a short time interval δt the unemployed worker receives income $b\delta t$, and a job offer arrives with probability $a\delta t$. The frictions studied in the economics of search are summarized in the arrival process. In the absence of frictions, $a \to \infty$. With frictions and search, $a > 0$; with no search, $a = 0$. A large part of the literature is devoted to specifying the arrival process, an issue addressed in Section The Aggregate Matching Function. The choice of search intensity has also been studied, by making a an increasing function of search effort, but this issue is not addressed here (see Pissarides, 2000: Chapter 5).

If a job offer arrives, the individual has the option of taking it, for an expected return $W_{t+\delta t}$; or not taking it and keeping instead return $U_{t+\delta t}$. If no offer arrives, the individual's return is $U_{t+\delta t}$. Therefore, with discount rate r, U_t satisfies the Bellman equation

$$U_t = b\delta t + a\delta t \frac{\max(W_{t+\delta t}, U_{t+\delta t})}{1 + r\delta t} + (1 - a\delta t)\frac{U_{t+\delta t}}{1 + r\delta t} \qquad [1]$$

Rearrangement of terms yields

$$rU_t = b + a(\max(W_{t+\delta t}, U_{t+\delta t}) - U_{t+\delta t}) + \frac{U_{t+\delta t} - U_t}{\delta t} \quad [2]$$

Taking the limit of eqn [2] as $\delta t \to \infty$, and omitting subscripts for convenience, yields

$$rU = b + a\,(\max\,(W, U) - U) + \dot{U} \quad [3]$$

where $\dot{U}$ denotes the rate of change of U.

Equation [3] is a fundamental equation in the economics of search. It can be given the interpretation of an arbitrage equation for the valuation of an asset in a perfect capital market with risk-free interest rate r. This asset yields coupon payment b and at some rate a, it gives its holder the option of a discrete change in its valuation, from U to W. Optimality requires that the option is taken (and the existing valuation given up) if $W \geq U$. The last term, $\dot{U}$, shows capital gains or losses due to changes in the market valuation of the asset. In most of the economics of labor-market search, however, research concentrates on 'steady states,' namely, on situations where the discount rate, transition rates, and income flows are all constant. With infinite horizons there are then stationary solutions to the valuation equations, obtained from eqn [3] with $\dot{U} = 0$.

One simple way of solving eqn [3] is to assume that employment is an 'absorbing state,' so when a job that offers wage w is accepted, it is kept for life. Then, $W = w/r$, and if the individual is sampling from a known wage offer distribution $F(w)$, the stationary version of eqn [3] satisfies

$$rU = b + a\left(\int \max\,(w/r, U)\mathrm{d}F(w) - U\right) \quad [4]$$

The option to accept a job offer is taken if $w/r \geq U$, giving the *reservation wage* equation.

$$\xi = rU \quad [5]$$

The reservation wage is defined as the minimum acceptable wage, and it is obtained as the solution to eqns [4] and [5].

Partial models of search and empirical research in the duration of unemployment have explored generalized forms of eqn [4] to derive the properties of transitions of individuals from unemployment to employment (see Devine and Kiefer, 1991). For a known $F(w)$ with upper support A, eqn [4] specializes to

$$\xi = b + \frac{a}{r}\int_{\xi}^{A}(w - \xi)\mathrm{d}F(w) \quad [6]$$

Various forms of eqn [6] have been estimated by the empirical literature or used in the construction of partial models of the labor market. The transition from unemployment to employment (the unemployment 'hazard rate') is $a(1 - F(\xi))$ and it depends both on the arrival of offers and on the individual's reservation wage. a, r, and the parameters of the wage offer distribution can be made to depend on the individual's characteristics. The empirical literature has generally found that unemployment compensation acts as a disincentive on individual transitions through the influence of b on the reservation wage, but the effect is not strong. The offer arrival rate increases the hazard rate, despite the fact that the reservation wage increases in a. A number of personal characteristics influence reservation wages and transitions, including age, education, and race.

Two-Sided Matching for Given Wages

Recent work in the economics of search has focused mainly on the equilibrium implications of frictions and search decisions. An equilibrium model needs to specify the decisions of firms and solve for the offer arrival rate a. In addition, a mechanism is needed to ensure that search is an ongoing process. The latter is achieved by introducing a probability $\lambda\delta t$ that a negative shock will hit a job during a short time interval δt. When the negative shock arrives, the job is closed down ('destroyed'), and the worker has to search again to find another job. For the moment, λ is assumed to be a positive constant (see Section Job Destruction).

The Aggregate Matching Function

To derive the equilibrium offer arrival rate, suppose that at time t there are u unemployed workers and v vacant jobs. In a short time interval δt each unemployed worker moves to employment with probability $a\delta t$, so in a large market the total flow of workers from unemployment to employment, and the total flow of jobs from vacant state to production, are both $au\delta t$. A key assumption in the equilibrium literature is that the total flows satisfy an *aggregate matching function*. The aggregate matching function is a black box that gives the outcome of the search process in terms of the inputs into search. If the u unemployed workers are the only job seekers and they search with fixed intensity of one unit each, and firms also search with fixed intensity of one unit for each job vacancy, the matching function gives

$$m = m\,(u, v) \quad [7]$$

with m standing for the flow of matches, au. The function is usually assumed to be continuous and differentiable, with positive first partial derivatives and negative second derivatives, and to satisfy constant returns to scale (see Petrongolo and Pissarides, 2000, for a review). A commonly used matching function in the theoretical literature, derived from the assumption of uncoordinated random search, is the exponential

$$m = v\left(1 - e^{-ku/v}\right), \quad k > 0 \quad [8]$$

The empirical literature, however, estimates a log-linear (constant elasticity) form, which parallels the Cobb–Douglas production function specification, with the elasticity on unemployment estimated in the range 0.5 – 0.7.

The fact that job matching is pairwise implies that the transition rates of jobs and workers are related to Poisson processes. Given $au = m$, the rate at which workers find jobs is $a = m/u$. If q is the rate of arrival of workers to vacant jobs, then total job flows $vq = au$, and so $q = m/v$. The equilibrium literature generally ignores individual differences and treats the average rates m/u and m/v as the rates at which jobs and

workers, respectively, arrive to each searching worker and vacant job. By the properties of the matching function,

$$q = m\left(\frac{u}{v}, 1\right) \quad [9]$$

$$\equiv m\left(\theta^{-1}, 1\right) \equiv q(\theta) \quad [10]$$

with $q'(\theta) < 0$ and elasticity $-\eta(\theta) \in (-1, 0)$. Here, θ is a measure of the *tightness* of the market, of the ratio of the inputs of firms into search to the inputs of workers. Similarly, the transition rate of workers is

$$a = m\left(1, \frac{v}{u}\right) \equiv \theta q(\theta) \quad [11]$$

By the elasticity properties of $q(\theta)$, $\partial a/\partial\theta > 0$. In the steady state, the inverse of the transition rates, $1/q(\theta)$ and $1/\theta q(\theta)$, are the expected durations of a vacancy and unemployment, respectively.

The influence of tightness on the transition rates is independent of the level of wage rates. If there are more vacant jobs for each unemployed worker, the arrival rate of workers to the typical vacancy is lower and the arrival rate of job offers to the typical unemployed worker is higher, irrespective of the level of wages. When a worker and a firm meet and are considering whether or not to stay together, they are not likely to take into account the implications of their action for market tightness and the transition rates of other unmatched agents. For this reason, the influence of tightness on the transition rates is known as a *search externality*. Several papers in the economics of search have explored the efficiency properties of equilibrium given the existence of the externality (see Section Competitive Search and Diamond, 1982; Mortensen, 1982; Pissarides, 1984; Hosios, 1990).

Job Creation

A job is an asset owned by the firm and is valued in a perfect capital market characterized by the same risk-free interest rate r. Suppose that in order to recruit a worker, a firm has to bear set-up cost K to open a job vacancy and in addition has to pay a given flow cost c for the duration of the vacancy. The flow cost can be interpreted as an advertising and recruitment cost, or as the cost of having an unfilled position in what might be a complex business environment (which is not modeled).

Let V be the value of a vacant position and J the value of a filled one. Reasoning as in the case of the value of a job seeker, U, the Bellman equation satisfied by V is

$$rV = -c + q(\theta)(J - V) \quad [12]$$

The vacant job costs c and the firm is offered the option to take a worker at rate $q(\theta)$.

Since the firm has to pay set-up cost K to create a job, it will have an incentive to open a job if (and only if) $V \geq K$. The key assumption made about job creation is that the gains from job creation are always exhausted, so jobs are created up to the point where

$$V = K \quad [13]$$

Substitution of V from eqn [12] into eqn [13] yields

$$J = K + \frac{rK + c}{q(\theta)} \quad [14]$$

Competition requires that the expected present discounted value of profit when the worker arrives, the value of a filled job J, should be just sufficient to cover the initial cost K and the accumulated costs for the duration of the vacancy, interest on the initial outlay rK, and ongoing costs c for the expected duration of the vacancy, $1/q(\theta)$.

Let productivity be a constant p in all jobs and the wage rate a constant w. With break-up rate λ, the value of a job satisfies the Bellman equation

$$rJ = p - w - \lambda J \quad [15]$$

The flow of profit to the firm is $p - w$ until a negative shock arrives that reduces its value to 0. Replacing J in eqn [14] by its expression in eqn [15] yields the *job creation condition*

$$\frac{p - w}{r + \lambda} - K - \frac{rK + c}{q(\theta)} = 0 \quad [16]$$

Equation [16] determines θ for each w and parallels the conventional labor demand curve. A higher wage rate makes it more expensive for firms to open jobs, leading to lower market tightness. Frictions slow down the arrival of suitable workers to vacant jobs and so the firm incurs some additional recruitment costs. If the arrival rate is infinitely fast, as in Walrasian economics, $q(\theta)$ is infinite and the last term in eqn [16] disappears. The assumptions underlying eqn [13] ensure that at the margin, the recruitment cost is just covered.

Wage Setting

With search frictions, there is no supply of labor that can be equated with demand to give wages. The conventional supply of labor is constant here: there is a fixed number of workers in the market, which is usually normalized to unity, and each supplies a single unit of labor.

In search equilibrium, there are local monopoly rents. Firms and workers who are together can start production immediately. If they break up, they can start production only after they find another partner through an expensive process of search. The value of the search costs that they save by staying together correspond to a pure economic rent; they could be taken away from them and they would still stay together. Wages need to share those rents.

Two approaches dominate in the literature. The first and more commonly used approach employs the solution to a Nash bargaining problem (see Diamond, 1982; Pissarides, 2000). The Nash solution allocates the rents according to each side's 'threat points.' The threat points in this case are the returns from search, and the Nash solution gives to each side the same surplus over and above their expected returns from search. Generalizing this solution concept, wages are determined such that the net gain accruing to the worker from the match, $W - U$, is a fixed proportion β of the total surplus, the sum of the worker's and the firm's surplus, $J - V$. This sharing rule can be obtained as the maximization of the product

$$(W - U)^{\beta}(J - V)^{1-\beta}, \quad \beta \in (0, 1) \quad [17]$$

The coefficient β can be given the interpretation of bargaining strength, although strictly speaking, bargaining strength in the

conventional Nash solution is given by the threat points U and V (see Binmore et al., 1986, for an interpretation of β in terms of rates of time preference).

The second approach to wage determination postulates that the firm 'posts' a wage rate for the job, which the worker either takes or leaves. The posted wage may be above the worker's reservation wage because of some 'efficiency wage' type arguments, for example, in order to reduce labor turnover, encourage more effort or attract more job applicants.

Bargaining

The value of an employed worker, W, satisfies the Bellman equation.

$$rW = w - \lambda(W - U) \qquad [18]$$

The worker earns wage w and gives up the employment gain $W - U$ when the negative shock arrives. No worker has an incentive to quit into unemployment or search for another job whilst employed, for as long as $w \geq b$, which is assumed.

With eqns [15] and [17] in place, the Nash bargaining solution to eqn [18] gives the sharing rule

$$W - U = \beta(W - U + J - V) \qquad [19]$$

Making use of the value equations and sharing rule yields

$$w = rU + \beta(p - (r + \lambda)K - rU) \qquad [20]$$

$$= (1 - \beta)b + \beta[p - (r + \lambda)K + (rK + c)\theta] \qquad [21]$$

There is a premium on the reservation wage which depends on the worker's bargaining strength and the net surplus produced. Wages depend positively on unemployment income and the productivity of the job, the first because of the effect that unemployment income has on the cost of unemployment and the second because of the monopoly rents and bargaining. Wages also depend on market tightness. In more tight markets they are higher, because the expected duration of unemployment in the event of disagreement is less. Empirical evidence supporting this wage equation has been found by a number of authors (e.g., Blanchflower and Oswald, 1994), although it should be noted that similar wage equations can also be derived from other theoretical frameworks.

Equilibrium

Equation [21] replaces the conventional labor supply curve and closes the system. When combined with the job creation condition eqn [16] it gives unique solutions for wages and market tightness. A variety of intuitive properties are satisfied by this equilibrium. For example, higher labor productivity implies higher wages and tightness; higher unemployment income implies higher wages but lower tightness. It remains to obtain the employment rate in equilibrium.

The labor force size is fixed, so by appropriate normalizations, if at some time t unemployment is u_t, employment is $1 - u_t$. In a short time interval δt, $a_t u_t \delta t$ workers are matched and $\lambda(1 - u_t)\delta t$ workers lose their jobs. Given that $a_t = \theta_t q(\theta_t)$, the evolution of unemployment is given by

$$u_{t+\delta t} = u_t + \lambda\,(1 - u_t)\delta t - \theta_t q\,(\theta_t) u_t \delta t \qquad [22]$$

Dividing through by δt and taking the limit as $\delta t \to 0$ yields

$$\dot{u} = \lambda(1 - u) - \theta q\,(\theta) u \qquad [23]$$

Because the solution for θ is independent of u, this is a stable differential equation for unemployment with a unique equilibrium

$$u = \frac{\lambda}{\lambda + \theta q\,(\theta)} \qquad [24]$$

Equation [24] is often referred to as the Beveridge curve, after William Beveridge who first described such a 'frictional' equilibrium. Plotted in space with vacancies on the vertical axis and unemployment on the horizontal is a convex-to-the origin curve. In the early literature the impact of frictions on the labor market was measured by the distance of this curve from the origin (see also Pissarides, 2000; Blanchard and Diamond, 1989).

Wage Posting

Wage posting is an alternative to wage bargaining, with different implications for search equilibrium. The firm posts a wage for the job and the worker who searches it either takes it or leaves it. Three different models of wage posting are examined.

Single Offers, No Prior Information

Workers search sequentially one firm at a time, they discover the firm's offer after they have made contact and they have to accept it or reject it (with no recall) before they can sample another firm. The worker who contacts a firm that posts wage w_i has two options. Accept the wage offer of the firm and enjoy expected return W_i, obtained from eqn [18] for $w = w_i$, or reject it and continue search for return U. The firm that maximizes profit chooses w_i subject to $W_i \geq U$. Since the firm will have no incentive to offer the worker anything over and above the minimum required to make workers accept its offer, in this model wages are driven to the worker's reservation wage, $w_i = b$ (Diamond, 1971).

In terms of the bargaining solution, the 'Diamond' (see eqns [20, 21]) equilibrium requires $\beta = 0$. The model can then be solved as before, by replacing β by 0 in the job creation condition and wage equation. Tightness, and consequently unemployment, absorb all shocks other than those operating through unemployment income, which also change wages. (There is a paradox in this model, in that if wages are equal to unemployment income no worker will have an incentive to search.)

Competitive Search

The next model increases the amount of information that workers have before they contact the firm (Moen, 1997). Workers can see the wage posted by each firm but because of frictions they cannot be certain that they will get the job if they apply. If the probability of a job offer across firms is the same, all workers will apply for the highest-wage job. Queues will build up and this will reduce the probability of an offer. In equilibrium, the wage offer and queue characterizing each job have to balance each other out, so that all firms get applicants.

The length of the queue is derived from the matching process. The firm that posts wage w_i makes an offer on average after $1/q(\theta_i)$ periods and a job applicant gets an offer on average after $1/\theta_i q(\theta_i)$ periods. Implicit in this formulation is the assumption that more than one firm offers the same wage, and firms compete for the applicants at this wage. Workers apply to only one job at a time.

Suppose now there is a firm, or group of firms, such that when workers join their queue they derive expected income stream $\overline{U}$, the highest in the market. The constraint facing a firm when choosing its wage offer is that the worker who applies to it derives at least as much expected utility as $\overline{U}$. The expected profit of the firm that posts wage w_i solves

$$rV_i = -c + q(\theta_i)(J_i - V_i) \qquad [25]$$

$$rJ_i = p - w_i - \lambda J_i \qquad [26]$$

The worker's expected returns from applying to the firm posting this wage satisfy the system of equations

$$rU_i = b + \theta_i q(\theta_i)(W_i - U_i) \qquad [27]$$

$$rW_i = w_i - \lambda\left(W_i - \overline{U}\right) \qquad [28]$$

The firm chooses w_i to maximize V_i subject to $U_i \geq \overline{U}$. The first-order maximization conditions imply that all firms offer the same wage, which satisfies

$$W - U = \frac{\eta}{1-\eta}(J - V) \qquad [29]$$

Comparison of eqn [29] with eqn [19] shows that the solution is indeed similar to the Nash solution, but with the share of labor given by the (negative of the) elasticity of $q(\theta)$, (which is equal to the unemployment elasticity of the underlying matching function). The rest of the model can be solved as in the Nash case.

There is a special significance to the share of labor obtained in this formulation. In the case where wages are determined according to the Nash rules, the firm and worker choose the wage after they meet, so it is unlikely that they will internalize the search externalities; they do not take into account the effect of their choices on the transition rates of unmatched agents. It can be shown that with constant returns to scale there is a unique internalizing rule which requires $\beta = \eta$, the solution of the wage posting model considered here (Hosios, 1990; Pissarides, 1984, 2000). For this reason, this particular wage posting model is often called the *competitive search* equilibrium. The key assumption that gives efficiency is the relaxation of the informational restrictions on workers, which lets them know both the firm's wage offer and the length of the queue associated with it.

Wage Differentials

The third version of the wage posting model relaxes the assumption that workers have the choice of at most one wage offer at a time but does not allow workers knowledge of the wage offer before they apply (Burdett and Judd, 1983; Burdett and Mortensen, 1998; Montgomery, 1991). The easiest way to introduce this is to allow workers the possibility of search on the job, i.e., to let them continue looking for a better job after they accepted one. Suppose for simplicity that job offers arrive to searching workers at the same rate a, irrespective of whether they are employed or unemployed. Suppose also that job search is costless (except for the time cost) and job changing is costless. Then, if a worker is earning w now and another offer paying w' comes along, the worker accepts the new offer if (and only if) $w' > w$. The worker's reservation wage is the current wage.

Unemployment pays b, so no firm can pay below b and attract workers. Consider a firm that pays just above b. Anyone applying for a job from the state of unemployment will accept its offer, but no one else will. Employed job seekers will have no incentive to quit their jobs to work at a wage close to b. In addition, this firm's workers will be quitting to join other firms, which may be paying above b. So a firm paying a low wage will have high turnover and will be waiting long before it can fill its vacancies.

A firm paying a high wage will be attracting workers both from unemployment and from other firms paying less than itself. Moreover, it will not be losing workers to other firms. So high-wage firms will have fewer vacant positions.

Now suppose the two firms have access to the same technology. The low-wage firm enjoys a lot of profit from each position, but has a lot of vacant positions. The high-wage firm enjoys less profit from each position, but has them filled. It is possible to show under general conditions that high wage and low wage firms will co-exist in equilibrium.

Burdett and Mortensen (1998) show this by assuming that there is a distribution of wage offers for homogeneous labor, $F(w)$, and demonstrating that (1) no two firms will offer the same wage, (2) firms can choose any wage between the minimum b and a maximum $\overline{w}$, and enjoy the same profit in the steady state. The maximum is given by

$$\overline{w} = p - \left(\frac{\lambda}{a+\lambda}\right)^2 (p - b) \qquad [30]$$

where as before p is the productivity of each worker and λ is the job destruction rate.

The interesting result about wage posting in this model is that once the assumption that the worker can only consider one offer at a time is relaxed, a distribution of wage offers for homogeneous labor arises. The distribution satisfies some appealing properties. As $a \to 0$, the upper support tends to $\overline{w} = b$, the Diamond solution. At the other extreme, as $a \to \infty$, it can be shown that all wage offers converge to p, the competitive solution. Intuitively, $a = 0$ maximizes the frictions suffered by workers and $a = \infty$ eliminates them.

Job Destruction

A body of empirical literature shows that there is a lot of 'job churning,' with many jobs closing down and new ones opening to take their place. It is also found that both the job creation and job destruction rates, especially the latter, vary a lot over the cycle (see Leonard, 1987; Dunne et al., 1989; Davis et al., 1996). This is an issue addressed by search theorists. Returning to the model with a Nash wage rule, the job creation flow is the matching rate $m(u, v)$. The job creation *rate* is defined as the job creation flow divided by employment, $m(u, v)/(1 - u)$, which is

$$\frac{m(u,v)}{1-u} = \theta q(\theta)\frac{u}{1-u} \qquad [31]$$

Since both θ and u are endogenous variables of the model that respond to shocks, the model predicts a variable job creation rate that can be tested against the data (see Mortensen and Pissarides, 1994; Cole and Rogerson, 1999).

But the job destruction flow is $\lambda(1-u)$, so the job destruction rate is a constant λ, contrary to observation. Two alternative ways of making it variable are considered.

Idiosyncratic Shocks

In the discussion so far, the productivity of a job is p until a negative shock arrives that reduces it to zero. Generalizing this idea, suppose that although initially the productivity is p, when a shock arrives it changes it to some other value px. The component p is common to all jobs but x is specific to each job. It has distribution $G(x)$ in the range [0, 1]. New jobs start with specific productivity $x = 1$; over time shocks arrive at rate λ that transform this productivity to a value between 0 and 1, according to the distribution G. The firm has the choice of either continuing to produce at the new productivity, or closing the job down. The idea is that initially firms have a choice over their product type and technique and choose the combination that yields maximum productivity. Over time techniques are not reversible, so if the payoffs from a given choice change, the firm has the choice of either continuing in the new environment or destroying the job.

As in the case where workers are faced with take-it-or-leave-it choices from a given wage distribution, Mortensen and Pissarides (1994) show that when the firm has the choice of either taking a productivity or leaving it, its decision is governed by a reservation productivity, denoted R. The reservation productivity depends on all the parameters of the model. Profit maximization under the Nash solution to the wage bargain implies that both workers and firms agree about the optimal choice of R, i.e., which jobs should be closed and which should continue in operation. With knowledge of R, the flow of job closures generalizes to $\lambda G(R)(1-u)$, the fraction of jobs that get shocks below the reservation productivity. The job destruction rate then becomes $\lambda G(R)$, which responds to the parameters of the economy through the responses of R to shocks.

An interesting feature of the job creation and job destruction rates, which conforms to observation, is that because the job creation rate depends on unemployment, which is a slow-moving variable, whereas the job destruction rate does not depend on it, the job destruction rate is more volatile than the job creation rate. For example, a rise in general productivity p, associated with a positive cyclical shock, reduces job destruction immediately by reducing the reservation productivity, but increases job creation at first and then reduces it, as tightness rises at first but unemployment falls in response.

Technological Progress and Obsolescence

Another way of modeling job destruction borrows ideas from Schumpeter's theory of growth through creative destruction (see Aghion and Howitt, 1994; Caballero and Hammour, 1994). Jobs are again created at the best technology but once created, their technology cannot be updated. During technological progress, the owners of the jobs have the option of continuing in production with the initial technology or closing the job down and opening another, more advanced one. As new jobs are technologically more advanced, the wage offers that workers can get from outside improve over time. There comes a time when the worker's outside options have risen sufficiently to render the job obsolete.

Formally, the model can be set up as before, with the technology of the job fixed at the frontier technology at creation time and wages growing over time because of growth in the returns from search. The value of a job created at time 0 and becoming obsolete at T is

$$J_0 = \int_0^T e^{-(r+\lambda)t}[p(0) - w(t)]\mathrm{d}t \qquad [32]$$

As before, r is the discount rate and λ is the arrival rate of negative shocks that may lead to earlier job destruction. $p(0)$ is the initial best technology and $w(t)$ the growing wage rate. The job is destroyed when $w(t)$ reaches $p(0)$; i.e., the job life that maximizes J_0 is defined by $w(T^*) = p(0)$.

A useful restriction to have when there is growth is to assume that both unemployment income and the cost of recruitment grow at the exogenous rate of growth of the economy. As an example, consider the wage eqn [21] with the restriction $K = 0$ and $b(t) = be^{gt}$, $c(t) = ce^{gt}$, where g is the rate of growth of the economy. T^* then satisfies

$$e^{gTA*} = \frac{(1-\beta)p}{(1-\beta)b + \beta c\theta} \qquad [33]$$

Jobs are destroyed more frequently when growth is faster, when unemployment income is higher and when the tightness of the market is higher.

Job destruction in this model has two components, the jobs destroyed because of the arrival of shocks, $\lambda(1-u)$, and those destroyed because of obsolescence. The latter group was created T^* periods earlier and survived to age T^*, $\theta q(\theta)ue^{-\lambda T^*}$ (note that in the steady state the job creation flow is a constant $\theta q(\theta)u$). Therefore, the job destruction rate now is $\lambda + \theta q(\theta)ue^{-\lambda T^*}/(1-u)$, which varies in response to changes in T^* but also in response to changes in the job creation rate $\theta q(\theta_u)/(1-u)$.

Abstract

During the last 50 years, John R. Searle has developed influential views on fundamental research areas within and beyond philosophy. This article mainly focuses on Searle's contributions to three fields of research. In the first section, John Searle's concept of a speech act is tackled. Topic of the second section is Searle's theory of mind and of intentionality. Finally, the third part addresses Searle's 'Philosophy of Society' (a discipline, which broadly covers what nowadays also falls under the name of 'social ontology').

John Rogers Searle is currently Willis S. and Marion Slusser Professor of Philosophy at the University of California, Berkeley. Searle was born on 31 July 1932, in Denver, Colorado, and began his studies at the University of Wisconsin–Madison in 1949. In 1952, he was awarded a Rhodes Scholarship from the University of Oxford, where he obtained a BA in 1955. Before receiving his PhD in 1959, he served as a lecturer in philosophy at the Christ Church College, Oxford, where he came in contact with John L. Austin, Peter Strawson, and other important representatives of what has been labeled 'ordinary language philosophy.' Soon after receiving his doctorate, Searle started teaching at Berkeley. In the mid-1960s, he became the first tenured professor to join the Free Speech Movement (FSM). The FSM was a protesting group of students that, as one of its main achievements, managed to extend the student rights to a significant extent including the – previously banned – liberty to use the University campus for political activity and debate (this experience is described in his 1972 book).

Over the years, he has been granted a number of prestigious prizes and honors from numerous institutions, including the most recent Puffendorf Medal (Sweden) in 2006; the Mind and Brain Prize (Italy) in 2006; the National Humanities Medal (United States) in 2004; and the Jovellanos Prize (Spain) and Jean Nicod Prize (France) in 2000.

Philosophy of Language

In the philosophy of language, Searle developed a systematic theory built around a notion of speech acts that theoretically refines and improves the concept introduced by John L. Austin in the 1950s (see his 1962; and, before him, by Adolf Reinach in German phenomenology, cf his 1913). According to Austin (1962), every speech act is composed of a locutionary and an illocutionary act (and, in some cases, of a perlocutionary act). For instance, if Sam utters the words "I'll be there," then his act can be analyzed as follows: First, he is uttering a meaningful sentence, i.e., he is performing a locutionary act. The locutionary act is itself a complex act. Roughly, this consists in Sam producing certain sounds (*phonetic act*), in these sounds being used as *words* – i.e., in being used as belonging to the vocabulary and as conforming to the grammar of a natural language (*phatic act*) – and in these words being used with a sense and a reference (*rhetic act*). Second, in addition to the locutionary act, Sam is performing an illocutionary act, i.e., he is uttering a sentence with a certain force, e.g., he is promising, announcing, menacing, or forecasting that he will be there. Austin claims that the concepts of locutionary and illocutionary acts are mutually exclusive (i.e., it can never be the case that one act is at once a locutionary and an illocutionary act), but he also adds that every locutionary act presupposes an illocutionary one and vice versa. Third, with his utterance Sam also could have wanted to do something else, e.g., he could have wanted to warn the addressee. In this case, a third, perlocutionary act has been performed.

One of the considerations that lead Searle to dismiss key parts of Austin's analysis is the following. Suppose Sam is more explicit and says, "I promise that I will be there." In this case, the description of the locutionary act is also a description of the illocutionary act, for once one determines the meaning of the sentence, one also determines its force: "The description of the act as a happily performed locutionary act, since it involves the meaning of the sentence, is already a description of the illocutionary act, since a particular illocutionary act is determined by that meaning. They are one and the same act" (Searle, 1968: 407). This goes against Austin's thesis of a relation of mutual exclusivity between locutions and illocutions and motivates Searle in modifying Austin's analysis. In particular, he drops Austin's idea of rhetic acts and substitutes it with that of 'propositional act.' A propositional act expresses a *proposition* – which is conceived of as the truth-bearing content of the speech act.

Searle's introduction of the propositional act has three important consequences. First, the act-theoretic description finds 'utterance acts' (which encompass phonetic and phatic acts), propositional acts, and illocutionary acts as the building blocks of every speech act (Searle, 1969: 23f.). Second, the notion of proposition provides Searle with the possibility to distinguish the speaker's meaning from the conventional or sentence meaning. Contrary to what Paul Grice has argued, namely that the meaning of a sentence is to be defined solely in terms of the speaker's intention to produce some effect in the hearer by means of the recognition of this intention (cf Grice, 1957), Searle recognizes that – in addition to this meaning – the speaker's utterance expresses a proposition, which identifies the literal or sentence meaning of the utterance (Searle, 1969: 44f.; for Searle's most recent account of speaker's and sentence meaning, see his 2010: 73ff.).

 http://dx.doi.org/10.1016/B978-0-08-097086-8.61282-5

It should be noted, however, that Searle improved his theory over the years by arguing that sentence meaning is not absolutely context-free: according to his more recent view, basically all forms of representation (whether linguistic or not) go "on against a background of assumptions which are not and in most cases could not also be completely represented as part of or as presuppositions of the representation" (1979a: 131), i.e., they presuppose the Background. Searle's point is that there is no 'zero context' or 'null context' for the interpretation of sentences (Searle, 1979a: 117): for instance, "[i]f you consider the sentence 'Cut the grass!' you know that this is to be interpreted differently from 'Cut the cake!' If somebody tells me to cut the cake and I run over it with a lawn mower or they tell me to cut the grass and I rush and stab it with a knife, there is a very ordinary sense in which I did not do what I was told to do. Yet nothing in the literal meaning of those sentences blocks those wrong interpretations" (Searle, 1995: 130f.). The conclusion to be drawn from these examples is that we understand the verb of each sentence differently, because in each case our interpretation depends on the Background, i.e., it depends on a set of abilities and capacities that we acquired along the years and are now part of our mental equipment (see below for further details on this notion).

The third consequence is that the previous two points (the structure of a speech act and the role played in it by the notion of proposition) speak for the idea that one and the same proposition can be expressed in connection with different forces. For instance, the utterances of "Sam smokes habitually," "Does Sam smoke habitually?" and "Would that Sam smoked habitually" are used to perform different illocutionary acts that bear the same proposition. This insight is at the basis of Searle's notation:

$$F(p)$$

where 'F' indicates the force of an utterance and 'p' the proposition expressed. Improved with the concepts of 'illocutionary point or purpose,' 'expressed psychological state,' and 'direction of fit,' this notation is at the basis of Searle's taxonomy of speech acts (cf 1979b). The illocutionary point is what Searle also calls the 'essential condition' of a speech act and it roughly identifies the reason for which the act is performed. So, for example, the point of promises is to undertake an obligation, the point of a description is to match the world, etc. In addition to essential conditions, speech acts also have 'sincerity conditions.' They are sincere if the speaker actually has the psychological state he or she expresses. If one communicates something to someone, the speaker is taken to believe the information that he or she is conveying (and if the speaker does not have this belief, he or she is lying). Similarly, in the case of promises, sincere promises are those which the promisor also intends to honor. That is, every sincere speech act expresses a corresponding psychological state, the lack of which makes the act insincere.

The concept of 'direction of fit' (whose intuition Searle credits to Elizabeth Anscombe, cf her 1957, and whose term he took from Austin, cf his 1953) is intended to capture how the propositional content is supposed to relate to the world. There are three standard kinds of direction of fit (DoF) and one 'nonstandard' kind. The standard kinds are: the words-to-world, the world-to-words, and the double DoFs. The words-to-world DoF characterizes all that acts like descriptions, prognoses, hypotheses, etc., whose aim is to fit the world – Searle also says that in these cases, it is the responsibility of the words to fit the world (cf 2010: 28). The world-to-words DoF identifies all those acts where the responsibility of fitting lies on the world's side, so to speak – these are acts like orders, commands, questions, invitations, etc. Finally, the double DoF is a feature that qualifies the particular class of declarations: declarations have the power to generate facts by representing them as obtaining. For instance, if the officiant declares Sam and Sarah as husband and wife, Sam and Sarah *are* husband and wife. (In Section Philosophy of Society we will turn back to this point.) In addition to these kinds of DoF, there are also speech acts showing a nonstandard DoF: suppose you apologize for something, in this case the act simply *presupposes* that something has been the case (i.e., the event for which you are apologizing). Searle initially believed that these sorts of acts have no DoF at all (and hence spoke of a 'null' DoF, cf 1979a). Later he came to the idea that it is not true that they are not completely unrelated to the world; rather, this relation is *presupposed* (the new terminology is hence that of a "Presup [for: 'presupposition'] Fit," cf 2010: 29).

Another important contribution to speech act theory is the distinction Searle draws between the conventional and the rule-constituted dimension of every speech act. Austin put the notion of convention at the very core of the idea of a speech act (a speech act is a 'conventional or ritual' act, cf Austin, 1962: 14). By contrast, Searle contends that, of course, speech acts have conventional aspects, but these aspects are not the ultimate constituents of a speech act. Rather, these constitutive aspects are to be sought in the rules that define what a speech act is. So, for example, one can express one and the same promise with the French words 'je promets' and the English words 'I promise.' Expressing the promise in French or in English is a matter of convention and it is not a constitutive feature of the promise: by contrast, the fact that to promise something counts as the undertaking of an obligation is a constitutive feature of promises and, more precisely, it is a matter of rules. The rules that define speech acts are a particular kind of rules, they are 'constitutive rules' (cf Searle, 1969: 33ff.).

The easiest way to understand what constitutive rules are is to consider them in contradistinction with another kind of rules, i.e., the regulative rules. As the expression already suggests, regulative rules regulate a form of behavior that could have taken place also without these rules. Take driving as an example: the rule to drive on the right side of the street is regulative in the sense that the activity of driving does not logically depend on this rule (people can drive cars also without it). By contrast, constitutive rules make a given activity possible in the sense that without such rules one does not have even the possibility to engage in the activity at issue. Playing chess is the main example here: without the rules of chess, one could not play the game. Characteristically, constitutive rules have the form 'X counts as Y in context C' (e.g., 'to make an order counts as imposing an obligation to the addressee'), whereas regulative rules have the form of imperatives (e.g., 'officers must wear ties at dinner').

Philosophy of Mind

According to Searle, to be fully conclusive, the considerations on speech acts have to be supplemented by a theory of

intentionality. Although words and sentences refer to (or are about) objects and states of affairs, the sense of this reference or aboutness is not primitive; rather, it is secondary, or 'derived.' It is derived, Searle claims, because it presupposes that the *mind* has the power to refer to something. To put this idea differently: words and sentences refer to something because a mind *imposes* this power on them (cf Searle, 1983: 26ff.; one could also express this point by saying that the representational capacities of words and sentences are extrinsic, whereas the representational capacity of the mind is *intrinsic*, cf Searle, 1980b).

To characterize this power or this capacity of the mind, Searle employs the term 'intentionality,' which he uses in the technical sense with which it was (re)introduced by Franz Brentano in post-Kantian philosophy (cf Brentano, 1874), i.e., to denote the feature of mental states to refer to objects and states of affairs in the world. So, for instance, perceptions and beliefs are intentional because they are always about something. In this sense, 'intentionality' has no privileged link to that specific class of mental states encompassing intentions, although it can be said that intentions, too, are intentional since they are directed toward or are about something.

We said that intentionality is a property of the mind; this suggests that we first need to say something about the mind before addressing the more specific question about the nature of intentionality. According to a very influential approach in the philosophy of mind – call it the 'strong artificial intelligence' approach, cf Searle 1980a, or the 'computer functionalist' approach, cf Dennett 1978 – the mind is nothing other than a computer program implemented in brains. To function, computer programs require hardware and, in the case of the mind, the hardware is the brain: since the description of the hardware is not the description of a program, so the description of the brain is not that of the mind. Still, the mind is not an entity separated from the brain; it is merely the program running on hardware and can therefore be accounted for in terms of its inputs and outputs.

Searle rejects the 'strong artificial intelligent' approach by developing an argument known as the 'Chinese room' argument (Searle, 1980a). It is based on a thought experiment, which, in its compact form, runs as follows: imagine a person who understands no Chinese is locked in a room. From the outside, she is handed a batch of Chinese writings containing questions in Chinese (the 'inputs'). Inside the room, she finds another batch of Chinese scripts and a set of rules written in English (the 'program') telling how to correlate the symbols in the first batch with the symbols in the second (the output or 'answers'). The rules tell how to process the questions in such a way that it is not possible for an external observer to tell whether the answers have been formulated by a program or by a Chinese-speaking person. At this point, Searle asks whether the person locked in the room understands Chinese: the force of the argument is to show that, although the entire situation can be framed as if the person is processing some inputs according to a program, this is not the case: "[b]ecause the program is purely formal or syntactical and because minds have mental or semantic contents, any attempt to produce a mind purely with computer programs leaves out the essential features of the mind" (cf Searle, 1992: 45).

The Chinese room argument leaves us with a negative result: if the mind is not a computer program, what is it? Searle's strategy for answering to this question is to avoid any "obsolete seventeenth-century categories" (Searle, 2008a: 71), meaning allegedly antithetical categories such as 'mental,' 'physical,' 'mind,' 'body,' etc. Searle indeed formulates his answer in overt contrast to these dichotomies (cf Searle, 2008c: 152–160), by claiming that the mind and its features, such as intentionality and consciousness, are nothing other than biological phenomena. This position is labeled 'biological naturalism' (Searle, 1983: 264) and Searle overtly states that we still do not have a clear grasp on how exactly the brain's neurobiology causes mental states and "we are not likely to find the answer in the near future" (1998: 96).

The fulfillment of this research desideratum would not preclude the project of a science of consciousness, though. In fact, mental states are entities of the sort that could be characterized as intrinsically 'subjective.' They are subjective in two senses: according to the first, they are subjective because they are eminently first-person phenomena. That is to say, they have a qualitative shape that is there only for the subject having these mental states and which hence cannot be expressed in a third-person language (2002a: 39f.). (This first sense could be qualified as 'phenomenological,' although Searle has a rather critical stance toward phenomenology as a philosophical movement, cf Searle, 2008b, 2010: 30.) In addition, they are subjective in the ontological sense of the term, i.e., they are necessarily the mental states *of* someone (and in this sense are not ontologically objective, this property being defined as independency from a subject). Despite their ontological subjectivity, though, Searle claims that one can make *epistemically objective* statements about them. "Consider, for example, the statement, 'I now have a pain in my lower back.' That statement is completely objective in the sense that it is made true by the existence of an actual fact and is not dependent on any stance, attitudes, or opinions of observers [this dependency defining the notion of 'epistemic subjectivity,' A.S.]. However, the phenomenon itself, the actual pain itself, has a subjective mode of existence […]" (Searle, 1992: 94). A science of the mind is hence possible because objective statements about subjective entities like mental states are possible. As we will see, one of the features that most cogently characterize most mental states is their intentionality.

A useful way to map mental states is indeed by means of two properties: intentionality and consciousness. Mental states are either intentional or nonintentional (I see that it rains; I am nervous – although I do not know what I am nervous about) and they are either conscious or unconscious (I am conscious of being hungry now, but my belief that today is Thursday is not conscious). Searle hence admits the existence of unconscious mental states, but these have to be characterized as states which in principle might be or might have been conscious (in contrast to those states of the brain that are unconscious and can never became conscious; here Searle has in mind states such as the "secretion of the neurotransmitter norepinephrine into the synaptic cleft," cf 1998: 97). But what makes a given mental state intentional?

Intentional states can be analyzed into two parts: the type of state and its content. Following the notation already presented

for speech acts, one could picture the structure of intentional states in this way:

$$S(p)$$

where S points at the kind of the state (also called the 'mode' of the experience, i.e., its being a desire, a perception, an intention, etc.) and p pictures the content. (Generally the content is a proposition, but there are exceptions where the content is nominal or non-propositional – e.g., admiration for someone, see Searle, 1983: 34.) It is important to highlight that the content of a state is not that toward which the state is directed: intentional states are directed toward objects or states of affairs *through* or via their contents. (So, for instance, the presentation of Pegasus has a content, but it does not have an object.)

Like speech acts, intentional states, too, have a direction of fit: e.g., beliefs have a mind-to-world DoF, and intentions or desires have the world-to-mind DoF. Intentional states with a propositional content and a direction of fit are also said to *represent conditions of satisfaction* (on the specificity of this notion of 'representation,' see Searle, 1983: 12). Accordingly, beliefs, desires, etc. 'represent' their conditions of satisfaction in the sense that they represent those conditions, which must obtain in order for these states to be satisfied. If one believes that it is raining, the state of affairs that it is raining must obtain for the belief to be satisfied. Analogously, a desire represents its conditions of satisfaction and these are what, again, must obtain for the desire to be satisfied.

One of the most debated aspects of Searle's theory of intentionality concerns his claim that there is a primitive and irreducible form of intentionality, which is *collective*. That is to say, not only I – as an individual – can intend, accept, believe … *p*, but there is a sense in which one can say that *we* (collectively) intend, accept, believe … *p*. Searle argues that collective intentionality does not boil down to individual intentionality plus relevant cognitive relations – especially mutual beliefs – among individuals (cf 2002b; over the years, though, Searle would drop the irreducibility thesis for some forms of collective intentionality such as collective acceptance or recognition, cf 2010: 58). At the same time, though, Searle intends to avoid the ontological commitment toward group minds as bearers or owners of collective intentionality. How can both claims be squared?

Searle's suggestion is to locate collectivity in the mode or kind of the experience. For instance, the mental state of collectively intending to φ (where "φ" points to a kind of action like painting an house, playing chess or writing a paper) is such neither because of a particular *subject* of the intention nor because of a particular *content* of the intention. Rather, this mental state is such because it is a particular *kind* of intention: it is not a simple intending; it is *we* intending (or a cooperative intending; in Searle's own words: a collective-goal-by-means-of-singular-contribution-intending). Two consequences can be drawn from this idea: first, all forms of intentionality (collective intentionality included) are always of an *individual* mind: it is an individual who is *we*-intending to φ. Second, the individual can be fundamentally mistaken about his or her own mental states: e.g., if my *we*-intention brings me to act, but this *we*-intention has no counterpart (i.e., there is no other individual whose we-intention mashes with mine), then I am thinking to collectively φing, though in reality I am doing something completely different (2002b: 97f.).

All intentionality, and *a potiori* collective intentionality, is made possible by two elements: the Background and the Network. Although Searle himself admits never having been able to make a satisfactory and precise distinction between the Background and the Network (Searle, 2012: 19), these two notions can be roughly characterized as follows. The Network is intended as a network of interconnected mental states, which enable other mental states. In order to have a single perception, say, the perception of a car, one needs to have an entire series of beliefs: one needs to believe that cars are means of transportation, that generally they are driven by human beings on the earth's surface, etc. In contrast, the Background is a complex of 'capacities,' (abilities, dispositions, tendencies, and causal structures generally, 1995: 129) which is anchored in our neurophysiology. For instance, the *capacity* of speaking and understanding English or the *capacity* of playing baseball are a matter of Background (1995: 141ff.): in the beginning, the layperson first needs to think about every single step to be carried out for the practice to be successful. However, once the game is learned, i.e., once the person has acquired the corresponding capacity, the entire process goes smoothly and automatically: it is caused and guided by the Background.

Philosophy of Society

In recent contributions (most notably, in two books published in 1995 and 2010), Searle mainly focuses on a "new branch of philosophy that might be called 'The Philosophy of Society'" (Searle, 2010: 5). Such a new discipline, which broadly covers what nowadays also falls under the name 'social ontology,' has the ambition to provide an account of social reality by identifying the main principles that regulate its construction. Social reality does not exist independently of social beings and, hence, it can be said to be ontologically subjective. However, it is possible to make epistemically objective judgments about it. For instance, the fact that a given piece of paper is a €100 bill would not exist without social beings and their institutions, but the judgment that 'this piece of paper is a €100 bill' is not an arbitrary (or epistemically subjective) judgment.

Searle argues that there are three logical building blocks that are required for the construction of social reality (cf Searle, 2008d: 31). Two of them have been previously mentioned: constitutive rules (rules of the forms 'X counts as Y in context C,' that enable given practices) and collective intentionality (the power of the mind to do things together). Below, we will see how these elements enter into the picture of Searle's social ontology. The third element is the notion of function and that of assignment or imposition of function.

Searle stresses that functions are extrinsic or observer-relative features: strictly speaking, "nature knows nothing of functions" (1995: 14). To say that a given object has a given function (e.g., that the function of the heart is to pump blood) is to 'locate' the object into some system of values and to evaluate the object and its properties with respect to these values. If, for example, we consider a patient's heart in connection to the value of the patient's life, the heart is malfunctioning if it endangers the life of the patient, but "[i]f we thought the most important value in the world was to glorify God by making thumping noises, then the function of the heart would be to make a thumping noise, and the noisier heart would be the better heart" (1995: 15).

Some functions are nonagentive; others are agentive (for this taxonomy, cf 1995: 121). Generally, agentive functions indicate uses: the properties of being a screwdriver or being a paperweight indicate how a given object can be used. Nonagentive functions occur naturally (in the sense that one assigns the notion of purpose to a natural and causal process, e.g., the heart's function is to pump blood). Among the agentive functions, a further distinction can be drawn between causal and status functions. Causal functions are performed "*solely in virtue of causal and other brute features of the phenomena*" (1995: 123f.), e.g., the necessary conditions that an object has to fulfill in order to satisfy the function of being a screwdriver are its physical features (having a certain form, a certain robustness, etc.). By contrast, status functions ontologically do not rely on the physical features of their objects: they are "*performed only by way of collective acceptance*" (1995: 124). For instance, in order for something to be money, it is fairly irrelevant what features the physical object has. Money can be pieces of paper, cigarettes, squirrel pelts, etc., as long as it is collectively accepted that these objects are money. An object together with its status function is called an 'institutional fact' (e.g., this piece of paper being a $10 bill, Obama being the President of the United States, my laptop being property of the University of Copenhagen, etc.)

As we have seen, to exist or to obtain, institutional facts have to be collectively accepted and collective acceptance is a form of collective intentionality. Searle holds that all facts involving collective intentionality are social facts (1995: 37). For instance, when a group of hyenas is after a prey, their collective hunting is a social fact. So, what makes institutional facts so peculiar within the class of social facts? This question has different answers, but there are two features, which Searle seems to particularly stress in his work: the linguistic nature of institutional facts and the deontology they are able to generate.

In a broader sense, institutional facts are linguistic because they cannot exist without a linguistic system. Were there no creatures with a linguistic apparatus and linguistic competence, there would also be no institutional facts. "Consider the case of points scored in a game such as football. We say 'a touchdown counts six points.' Now, that is not a thought that anyone could have without linguistic symbols. But […] why? […] The answer, to put it simply, is that if you take away all the symbolic devices for representing points, there is nothing else there" (1995: 66). This goes not only for the game of football, but for all institutional facts – in fact, one should remember that these facts do not depend, for their existence, on the natural features of their constituting objects, and this suggests that a perfect description of the physical properties of the objects at issue would not say anything about their status functions.

This leads to a further consideration: institutional facts are linguistic – now in a narrower sense – because their very structure is linguistic. In a first version of his theory (1995), Searle argued that all institutional facts have the form 'X counts as Y in context C,' where X is a given object, generally a nonsocial one, and Y the term for the status function (note, however, that since the formula can be iterated, X could also point at a social object, as instance consider the case where a University's professor counts as the Dean of her Department). In his more recent contribution (2010), Searle – still holding that the formula captures a fundamental feature of institutional facts – restricts its validity only to a subclass of institutional facts. In addition to 'X counts as Y in context C'-structured facts, he introduces the idea of 'free-standing Y terms' to accommodate those facts where apparently no X figures in their structure (think of blindfolded chess, electronic money, or corporations as examples of such facts, 2010: 20f.). The introduction of these sorts of facts asks for further consideration: Searle needs to say something more about facts whose existence is not anchored, as it were, to the existence of a material object (of an X) and which, hence, seem to be made out of thin air.

To provide an account for these facts, Searle recurs to the notion of declaration that he previously developed in his speech-act theoretic work. Declarations were defined as speech acts with a double DoF: they create a reality by means of representing it as existing. Analogously, one can create institutional facts by performing collective declarations of the form:

> We make it the case by Declaration that the Y status function exists in context C.

Searle conceives of such a declarative mechanism as underlying the creation of *all* institutional facts. Accordingly, in the case of Ys assigned to Xs, we have a declaration of this kind:

> We make it the case by Declaration that X has the status Y […] in C.
> Searle, 2010: 99

Declarations hence acquire a central role in Searle's social ontology: "God can create light by saying 'Let there be light!' Well, we cannot create light but we have a similar remarkable capacity. We can create boundaries, kings, and corporations by saying something equivalent to 'Let this be a boundary!' 'Let the oldest son be the king!' 'Let there be a corporation!'" (Searle, 2010: 100).

A second feature that characterizes institutional facts is the deontology they generate. Searle's idea is that, whatever the metaphysical intricacies of boundaries, kings and corporations are, all these entities have a set of deontic powers attached to them, including rights, obligations, entitlements, etc. Boundaries should not be crossed without authorization, kings can declare war, corporations can enter contracts, etc. Indeed, Searle claims that *all* status functions (and, *a potiori*, *all* institutional facts, these being facts constituted by status functions) imply deontic powers (Searle, 2010: 23). That is, the status 'function itself' is to be "spelled out as a set of deontic powers" (Searle, 2010: 99) or, even more clearly, "[…] the [status] function is defined in terms of [deontic] power […]" (Searle, 1997: 451). It is hence remarkable that the complex metaphysics of such intentionality-dependent, institutional facts could also be considered as eventually boiling down to "[…] deontic phenomena" which "are not reducible to something more primitive and simple" (Searle, 1995: 70).

These deontologies provide desire-independent reasons for actions. If a person is thirsty and sees a glass of beer, the desire to quench his or her thirst might drive that person to reach for the glass and drink. Still, if someone else has ordered this glass of beer, such institutional fact has attached a deontology (an obligation) providing the desire-independent reason for

action, not to drink from others' glasses (for an example along the same lines, cf 2001: 27). According to Searle (2001), the distinction between desire-dependent and desire-independent reasons for action is essential in order to give an adequate account of (especially) practical rationality and to amend some of the weak points of what he calls the Classical Model of Rationality (a sort of more or less explicit and paradigmatic description of rationality in terms of payoff maximization, cf 2001: 5ff.).

The considerations on desire-independent reasons for action have to be understood in light of a main purpose that seems to have steered large parts of Searle's philosophical work: the attempt to make sense of concepts like language, mind, institutions, freedom of will, etc., in a world he describes as entirely composed of atoms and molecules.

Reception

During the last 50 years, John Searle has developed influential views on fundamental research areas within and beyond philosophy. Many of his publications are by now considered classics in the field of philosophy, and his ideas can be said to have profoundly impacted the scientific understanding of language, mind, and the social world.

His many works devoted to speech act theory have substantially contributed to the development of pragmatics and to its establishment as standing area of research within the philosophy of language. His book on *Intentionality* was one of the main factors that informed the process that put the mind and other mentalistic notions (like intentionality) back at the center of philosophical debates. Furthermore, the emergence of social ontology as a new field of research and the growing interest in intentionalistic explanations of collective phenomena can be seen as closely and directly linked to his more recent contributions about 'the philosophy of society.'

Second Demographic Transition

James M Raymo, University of Wisconsin-Madison, Madison, WI, USA

This article is a revision of the previous edition article by D.J. van de Kaa, volume 5, pp. 3486–3488, © 2001, Elsevier Ltd.

Abstract

The Second Demographic Transition (SDT) is a term used to describe dynamic interrelationships between fertility rates, a constellation of innovative demographic behaviors, and changing values in countries characterized by sustained below-replacement fertility. Key demographic changes accompanying the emergence of very low fertility include delayed marriage and childbearing, and substantial increases in cohabitation, nonmarital fertility, childlessness, maternal employment, and divorce. The core shift in values associated with the SDT involves movement away from viewing marriage and childbearing as either unquestioned or obligatory toward a life orientation in which family formation is something purposively chosen for its role in self-actualization.

The Second Demographic Transition (SDT) is a term first used in the mid-1980s by Ron Lesthaeghe and Dirk van de Kaa to describe the emergence of sustained below-replacement fertility and an accompanying 'package' of new behaviors and attitudes in several European countries (Lesthaeghe and Van de Kaa, 1986; Van de Kaa, 1987). Their reference to a 'second' transition was motivated primarily by the fact that, in contrast to a central assumption of classic demographic transition theory, period fertility rates had fallen well below replacement levels in several countries. At the core of the SDT framework is an emphasis on dynamic interrelationships between fertility rates, a constellation of 'innovative' demographic behaviors, and changes in values and life orientation. In addition to below-replacement fertility, the demographic changes commonly described as part of the SDT include delayed marriage, delayed childbearing, childlessness, increases in the proportion who never marry, and substantial increases in nonmarital cohabitation, nonmarital fertility (including fertility within cohabiting unions), maternal employment, and divorce (Lesthaeghe, 1995; Lesthaeghe and Moors, 2000; Van de Kaa, 1987).

The range of potential explanations offered for the demographic changes associated with the SDT is broad and includes shifting attitudes and values, changes in contraceptive technology, and changes in the economic opportunities and roles of men and women driven by educational expansion and economic change (e.g., Bumpass, 1990; Lesthaeghe, 1995, 1998; Lesthaeghe and Moors, 2000; McDonald, 2000). The role of shifting attitudes and values, in particular, has been central to the SDT framework from the beginning. In very general terms, the core shift in values or life orientation has been described as a move away from viewing marriage and childbearing as either an unquestioned part of life or a duty to family and society (as in the first demographic transition) toward a view that family formation is something purposively chosen for its role in self-actualization. In the SDT framework, the process by which this emerging valuation of satisfying 'higher order needs' and new family behaviors evolve is viewed as cyclical. Initially, the decline in fertility and the emergence of new family behaviors is driven by changes in values including declining familistic altruism, increasing individuation, secularization, antiauthoritarianism, and rising consumption aspirations. Innovators at the forefront of these shifting values self-select into new family behaviors including postponement or avoidance of marriage and parenthood and these experiences reinforce the underlying attitudes and values while the new patterns of demographic behavior become more widely accepted and diffuse throughout population (Lesthaeghe and Surkyn, 1988; Surkyn and Lesthaeghe, 2004).

The initial formulation of the SDT framework sought to explain observed demographic changes in a small number of countries in North and Western Europe. As the framework developed over time, increased emphasis has been placed on understanding the SDT as a broader phenomenon and on documenting its spread to other regions. Related empirical research has focused on (1) developing rankings or typologies to classify countries according to their stage of progression through the SDT (Lesthaeghe, 1995; Lesthaeghe and Moors, 2000; Sobotka, 2008), (2) describing variation across low-fertility countries in the pace and nature of changes associated with the SDT (Sobotka, 2008), and (3) evaluating whether specific countries should be considered SDT countries (Atoh et al., 2004; Lesthaeghe and Neidert, 2006). This work has shown that the levels of key demographic indicators and attitudes associated with the SDT tend to cluster in different areas, with the Scandinavian countries most 'advanced' in terms of SDT characteristics and Southern European countries less far along. It is also clear that the constellation of demographic behaviors associated with the SDT varies, with low fertility and the full package of new family behaviors emerging more or less in tandem in the original SDT countries, in piecemeal fashion in other countries (e.g., Southern Europe and East Asia), or following rapid fertility collapse after major political and economic change in Central and Eastern Europe.

Just as regional variation in the transition from high fertility to low fertility provided important insights into the roles played by language, social capital, networks, and diffusion processes, research on the transition from low to very low fertility has made use of variation in the pace and nature of

associated family changes to better understand the influence of social, historical, economic, and political context. For example, historical and cultural differences in the strength of family ties and patterns of departure from the parental home have been linked to regional differences in the spread of nonmarital cohabiting unions, especially the low prevalence in Italy and other Southern European countries (Reher, 1998). Similarly, the very low prevalence of nonmarital childbearing in low-fertility East Asian countries is thought to reflect the continued strength of social stigma and legal discrimination against 'illegitimate' children (Rindfuss et al., 2004). Social and economic factors that combine to make work–family balance more difficult for women in some societies than in others have been linked to regional differences in marriage, fertility, and married women's labor force attachment (McDonald, 2000; Rindfuss et al., 2003). Within the US, substantial regional variation in fertility and demographic behaviors associated with the SDT has been linked to regional differences in religion and attitudes (Lesthaeghe and Neidert, 2006).

Research during the past decade has increasingly emphasized socioeconomic differences in family behaviors associated with the SDT and the implications of those differences for inequality and the reproduction of disadvantage. In contrast to earlier research emphasizing the role of highly educated demographic and attitudinal innovators, this new work has focused on the growing concentration of demographic behaviors with potentially negative implications for subsequent well-being at the lower end of the socioeconomic spectrum. The impetus for this work emerged primarily from the US where it has become increasingly clear that some behaviors associated with the SDT such as nonmarital childbearing, nonmarital unions, and union dissolution are increasingly concentrated among those with the most limited socioeconomic resources (McLanahan and Percheski, 2008). In an influential paper published in 2004, Sara McLanahan portrayed this pattern of family bifurcation as a key feature of the SDT and highlighted its role in rising inequality, especially in children's resources. Building upon this work and accumulated evidence from a range of countries including those in Central and Eastern Europe, Sobotka (2008) suggests that there may be two pathways to the SDT. One is the original depiction in which highly educated innovators adopt new behaviors and associated attitudes/values which then diffuse throughout the population (as with fertility regulation in the classic demographic transition framework). In the second pathway, economic uncertainty or other structural conditions that make conventional family patterns difficult to achieve result in emergence of cohabitation, nonmarital childbearing, and other SDT behaviors among the more disadvantaged segments of the population before spreading more broadly. Careful empirical evaluation of this argument is a relatively new area of research and findings to date are mixed, with some finding consistent patterns in nonmarital childbearing in Europe (Perelli-Harris et al., 2010) while others find little evidence that educational differences in divorce are changing in a similar way Härkönen and Dronkers (2006).

The SDT framework is widely referenced but consensus regarding its interpretation is not universal. Some have questioned the appropriateness of the term SDT, arguing that recent trends, especially sustained below-replacement fertility, should be seen as an extension in the longer demographic transition process (Cliquet, 1991) or that the changes observed do not merit the term 'transition' (Coleman, 2004). Others have raised questions about the permanence of changes, suggesting that below-replacement fertility may be a temporary phenomenon generated by widespread postponement of family formation. The idea that period fertility rates will rebound when those currently postponing family formation begin to have children has inspired important efforts to disentangle the impact on the Total Fertility Rate (TFR) of changes in the timing of fertility – tempo effects and reductions in the number of children women will ever have – quantum effects (Bongaarts and Feeney, 2000). The return to near-replacement fertility in some SDT countries like France and Sweden appear consistent with a view of the SDT as a transitory phenomenon and the absence of some key features of the SDT in very low-fertility countries in Southern Europe and East Asia highlights the limited generalizability of the SDT as it was originally depicted. Despite these questions and critiques, the term SDT is now widely used by demographers as a convenient and informative means of summarizing recent demographic trends in societies characterized by very low fertility. In Sobotka's (2008: p. 213) words, "the second demographic transition seems to be particularly useful as an umbrella concept that encompasses a broad range of interrelated changes in sexuality, family, and partnership behaviours and attitudes, as well as a massive postponement of parenthood."

What is the future of the SDT? Evidence of fertility recuperation at older ages in many countries (Lesthaeghe, 2010) suggests that below-replacement fertility, or at least lowest-low fertility, may be a temporary phenomenon. However, it does appear that many of the new family forms, especially the separation of marriage and childbearing, and accompanying changes in attitudes and values are here to stay (Sobotka, 2008). Moving forward, it seems likely that efforts to evaluate the idea of an SDT or to place countries on an SDT continuum will give way to efforts to evaluate the broader and longer-term implications of the fundamental demographic changes that have come to be associated with the SDT. For example, it is clear that prolonged periods of below-replacement fertility will result in rapid population aging and population decline. Related policy responses, including pronatalist policies, work–family balance policies, and migration and guest worker policies are all of increasing interest to demographers. The same is true of the changed family landscape and new attitudes toward children and family life, including perhaps permanently altered preferences regarding the relationship between marriage and childbearing, the timing of family formation, and desired family size. Finally, because many of the family behaviors associated with the SDT have important implications for economic well-being and the intergenerational transmission of dis/advantage, efforts to understand how these changes impact poverty, stratification, and social mobility, and how these relationships differ across countries characterized by different social, economic, and policy contexts, will likely be a core focus of demographers in the years to come.

Abstract

This contribution provides an overview of second language acquisition research from a psycholinguistic perspective. The overview is mainly focused on cross-language interactions during word and sentence production and comprehension at different points in the second-language acquisition process. The main conclusion is that language learning is interactive and dynamic. Because of this interactivity and dynamicity, the process and outcome of second-language acquisition can be influenced by many different factors, like the similarity between the first and second language, the learning context, learner motivations, the age at which a second language is learnt, and the learner's language proficiency and background.

Introduction and Historical Context

The world counts close to 7000 known living languages spread over more than 200 countries (Lewis, 2009). It is therefore not surprising that the number of people in the world speaking multiple languages easily outperforms that of people speaking only one language (e.g., Gardner-Chloros, 2009; Grosjean, 2008), and that roughly two-thirds of all children in the world grow up in a bilingual environment (e.g., Bhatia, 2004; Crystal, 2003). In addition, because of the growing influence of international mass media, global communication through the internet, and increased mobility across countries, it is important for many people to learn to speak other languages in addition to their first language.

There are many types of second-language learners. In addition to the typical school pupil who is taught a second language for educational purposes, there are migrants, children of migrants, expats, children who are enrolled in bilingual education programs, international students, adopted children, and people who speak a dialect in addition to the national majority language. It can be concluded from this that the context in which a second language is learnt, the motivations to learn a second language, the age at which a second language is learnt, as well as the social and linguistic background of the language learner can differ widely. These are all factors that can influence the second language acquisition (SLA) process (see, e.g., Doughty and Long, 2003; Gass and Mackey, 2012; Robinson, 2013, for overviews).

It is difficult to say exactly when the study of SLA began, but an important work that fueled much early thinking was *Linguistics across Cultures* by Robert Lado (1957). Building on behaviorist theories of language learning, Lado proposed that difficulty of second-language learning is based on the distance between the native language and the target language. Elements that are similar between languages will be relatively easy to learn whereas elements that are dissimilar will be relatively difficult to learn. Later, Lado's views were questioned by researchers like Corder (1967) and Dulay and Burt (1974), who argued that the type of errors second-language learners make or the developmental sequences of SLA cannot wholly be attributed to the linguistic distance between the native language and the target language. Over the last decades, second-language research has evolved into a research field that has built on many different research disciplines, ranging from general linguistics to cognitive psychology and from sociolinguistics to educational science, in which SLA is often characterized as a complex and dynamic process that is influenced by a multitude of factors (e.g., De Bot et al., 2005; Doughty and Long, 2003; Ellis, 1994; Gass and Mackey, 2012; Robinson, 2013; Robinson and Ellis, 2008).

Much research on SLA is closely tied to research on bilingualism. The term 'bilingual,' like 'multilingual,' is often loosely used as referring to a speaker of two or more languages (see Appel and Muysken, 1987; Bhatia and Ritchie, 2013; Kroll and de Groot, 2005; Li Wei, 2007. for overviews). A central question in the field of bilingual language processing is how and to what extent a bilingual's languages interact with each other during language use. An important instigator of this research was Uriel Weinreich, who studied the extent to which a bilingual's languages compete with each other and are stored in the brain as a function of language dominance, proficiency, and use (Weinreich, 1953). This role of language dominance and proficiency is still central in current research on the bilingual speaker, for instance on issues like cross-language interactions in language production and comprehension (e.g., Dijkstra, 2009; Kroll et al., 2012; Van Hell and Tanner, 2012), cognitive control of languages in balanced and unbalanced bilinguals (e.g., Christoffels et al., 2007; Green, 1998), and the consequences of bilingualism for nonlinguistic aspects of memory and executive functions (e.g., Bialystok et al., 2012).

Considering the thematic relatedness between bilingual language processing and SLA, it is becoming more and more difficult to distinguish research on bilingualism from research on SLA. Cross-language interactions during language production and comprehension, for instance, have not only been studied from a bilingual language processing perspective, but

also from an SLA perspective, in which it is often termed *language transfer* or *crosslinguistic influence* (e.g., Jarvis and Pavlenko, 2008; Kellerman and Sharwood Smith, 1986; MacWhinney, 2008; Odlin, 1989). Likewise, more and more studies on bilingual processing focus on proficiency and learning processes and thus make the link with SLA research (see, e.g., Kroll and de Groot, 2005; de Groot, 2011, for overviews). This close connection between SLA and bilingual processing will also be the starting point of the present contribution, in which we present a perspective on SLA inspired by studies on bilingual language processing.

Core Notions in SLA and Processing

Two fundamental notions with respect to language learning are that it is both *interactive* and *dynamic*. Language learning is *interactive*, because it is affected by what the learners already know about their native language and other languages. Methods for teaching a foreign language (FL) can only be optimized if the underlying mechanisms of such interactions are clear. If learners of an FL depend heavily on the rules and representations they already have in their native language, learning will be different when it takes place at a later age (when L1 is firmly established) relative to early in life (when L1 is still under development). Psycholinguistic research in the last two decades has provided evidence that most sorts of language information, for instance, with respect to pronunciation (phonetics/phonology), words (lexicology), word formation and grammar (morphosyntax), and meaning (semantics) in bilinguals are not stored in long-term memory stores that are separate for each language but are integrated across languages (see, e.g., De Groot, 2011, for a balanced review of the data). Furthermore, during processing, information from these stores appears to be accessed in a language-independent way. As a consequence, information of different languages interacts at all linguistic levels, for instance during the processing of words and sentences. Research looking into these interactions has considered situations in which language processing converges (i.e., in the case of crosslinguistic similarities between languages) and in which it diverges (in case of crosslinguistic differences between languages).

The second fundamental notion is that language learning is *dynamic*. The language system goes through profound changes during the lifespan and it is quite sensitive to prolonged and momentary changes in the environment (Grosjean and Li, 2013, p. 10). To describe the waxing and waning of whole languages and their various representations, the *activation metaphor* is well suited. Words and grammar of a language can be more or less *active* at certain moments in time. Many researchers assume that words are characterized by a *resting-level activation* when they are not used and an *activation rate* when they are, which is dependent on how often they are used. Thus, when words are encountered during reading, listening, or speaking, they become active and available faster or slower, again depending on their frequency of usage. Because words in a second language have typically been learned later in life (i.e., they have a later age of acquisition) and are used less than words of a first language, their subjective frequency is lower, resulting in more effortful, slower, and less accurate processing (cf Grosjean and Li, 2013, p. 224). It is further assumed that when multiple languages are present, there may be simultaneous activation or *co-activation* of elements (words, sentences) of different languages, due to lexical or structural (syntactic) overlap. In the following section, we will consider the interactive activations of languages at word and sentence levels in more detail. This will be followed by a consideration of the dynamic aspects of language learning across the life span.

The Interaction of Languages

Interactions at the Word Level

At the *word* level, many studies have investigated how words are processed that have form overlap between languages. Words that are similar in their orthographic or phonological form between languages, but that differ in meaning at the same time, are called 'false friends' (also: interlingual homographs or interlingual homophones). Examples are words like COIN (English) – COIN (French, meaning 'corner') and SLIM (English) – SLIM (Dutch, meaning 'cunning'). Words that are similar in form and in meaning are called 'cognates' (such words usually have a common etymology or are borrowings in one of the languages). So-called 'identical cognates' are translation equivalents that are orthographically identical and often phonologically very similar across languages, like FILM (English) – FILM (Dutch, French, Polish, and many other languages) (Peeters et al., 2013). 'Nonidentical cognates' are translation equivalents that are crosslinguistically less similar in their orthography and phonology, like TOMATO (English) – TOMAAT (Dutch) – TOMATE (French) – ΔΟΜΑΤΑ (Greek, pronounced as /doma:ta:/). Studies with false friends have shown that their processing is typically slowed down relative to matched one-language control words (Dijkstra, 2005) and that the degree of interference depends on the relative frequency of usage of the false friends in the associated languages. The strongest interference effects have been observed for low-frequency L2 words with high-frequency L1 false friends (e.g., Dijkstra et al., 1998; Smits et al., 2006). Studies with cognates have reported that these are usually processed faster than comparable control words ('cognate facilitation') and that the degree of facilitation depends on the cognate's degree of crosslinguistic similarity. This holds for words in isolation (Dijkstra et al., 2010) and in sentences (van Assche et al., 2011). Like in false friends, the relative frequency of usage of the cognate in a language also plays a role (Peeters et al., 2013).

The difference in processing between false friends and cognates has been explained as a consequence of their representational differences. It is assumed that for both false friends and cognates, form representations in both languages are co-activated (e.g., SLIM activates both an English and a Dutch form representation). In false friends, the competition between the co-activated form representations results in slower recognition. In cognates, two form representations are also assumed to become co-activated. However, cognates are assumed to have a meaning representation that is at least partially shared between languages. This representation is co-activated by both form representations and benefits cognate

processing relative to control words (Dijkstra et al., 2010; Voga and Grainger, 2007).

The cross-language interactions described above turn out to be influenced by *relative language proficiency*. Van Hell and Dijkstra (2002) tested the size of the 'cognate facilitation' effect in trilinguals who differed in their proficiency of the third language. When Dutch (L1) university students with English as a second language (L2) and French as a third language (L3) performed a Dutch lexical decision task, a cognate facilitation effect was found for Dutch–English cognates, but not for Dutch–French cognates. Because the trilingual participants all were native speakers of Dutch (L1) with a higher proficiency in English than in French, this was to be expected. In a second experiment, trilinguals with a much higher level of French proficiency were recruited (i.e., Dutch university students of French). For this participant group, cognate facilitation effects in Dutch were obtained for both Dutch–English (L1–L2) and Dutch–French (L1–L3) cognates. Therefore, relative proficiency in another language (L2 or L3) affects the size of the cognate facilitation effect in L1, at least for this population of adult participants.

With respect to L2 word learning, cognates are prominent in many language courses, because they are easier to acquire than control words: their form and meaning overlap with L1 representations makes them easier to store and remember. When pairs of European languages are compared with respect to their lexicons, large numbers of cognates are found and much smaller numbers of false friends (Schepens et al., 2012, 2013). Thus, in spite of the misleading form overlap in the case of false friends, the relative prominence of cognate words in the initial phases of a language learning curriculum may indeed be beneficial to the learner.

A model that been proposed to understand the interactions and dynamics of language learning and language processing is the Revised Hierarchical Model (RHM; Kroll and Stewart, 1994). The RHM assumes that information about words is stored both in a lexical memory (for word forms) and in a conceptual memory (for word meanings). The conceptual memory is nonlinguistic in nature, implying that meanings of words can be shared by words from different languages. For instance, TOMATO (English) and TOMAAT (Dutch) map onto one and the same meaning. In a late L2 learner, strong connections between word forms of the native language L1 and their meanings have already been established. In the first phases of L2 learning, the L2 form representations will not be very strong, and the same holds for their connections to meaning. Because of these weak representations and connections, it might be quicker not to look up the L2 word's meaning in the lexicon directly (concept mediation), but indirectly via the stronger L1 representations and their strong connections to meaning (word association). Depending on the L2 teaching method, a learner may already have forged links between L2 and L1 form representations, for instance, between HORSE (L2) and PAARD (L1) in a Dutch learner of English (e.g., Comesaña et al., 2009). Thus, it might be faster to find the meaning of HORSE via the form representation of PAARD rather than via the form-meaning connection of HORSE itself. In later stages of learning, the L2 word form HORSE and its connection to meaning are strengthened by more frequent use. Accordingly, the direct route to meaning would become more prominent.

The RHM has inspired hundreds of studies over the last 15 years. In addition to findings of the predicted development from word association to concept mediation (e.g., Talamas et al., 1999), an increasing number of studies has found early concept mediation effects in L2 word learning (Altarriba and Mathis, 1997; Brenders et al., under revision; Comesaña et al., 2009; de Groot and Poot, 1997). To gain more insight into the relative contribution of concept mediation and word association in different stages of SLA, computational modeling of the RHM's assumptions would be useful (a first attempt to do so is Multilink, Dijkstra and Rekké, 2010).

Complementary to the RHM model, another model for language interactions at the word level that has recently been applied to L2 acquisition issues is the Bilingual Interactive Activation (Plus) Model (BIA+). The BIA+ model (Dijkstra and Van Heuven, 1998, 2002; Van Heuven et al., 1998) extends the Interactive Activation model for word recognition from McClelland and Rumelhart (1981, 1988). This symbolic (or localist) connectionist model proposes that word recognition entails the activation and de-activation of representations for letter features, letters, and words. During the recognition process, words that are similar to the input letter string compete for recognition (e.g., the input BIKE also leads to activation of LIKE, HIKE, and BAKE, so-called 'neighbors'). In addition, the task to be performed (e.g., name the word or decide whether a letter string is a word or not) codetermines the ultimate response time.

Another important determinant of the model's behavior is the lexicon that is incorporated, which can be monolingual or bilingual. Clearly, for bilingual learners, words from a second language will be included depending on their current L2 proficiency. More proficient learners will know more L2 words. In addition, the subjective frequency of usage of those words will become higher when the second language is used more often. This characterization of L2 learning makes it clear that at every stage of learning, the learners' lexicon can be considered as a combination of all L1 words with a particular frequency and a (typically smaller) set of L2 words with a particular frequency. Dijkstra et al. (2012) conducted simulations with the BIA+ model for different stages of learning, i.e., with a changing lexicon. These simulations showed that for Dutch as a native language and English as a second language, word recognition in Dutch was relatively unaffected by the increasingly stronger English, while the new English words were still recognized at reasonably normal response times.

Dijkstra et al. (2012) also report a series of simulations with a distributed connectionist model for word learning that extends an earlier model by Thomas (1997). This Revised Bilingual Single Network model assumes that learners build word-form representations for words in a new language that are linked to semantic representations during learning. Using a biologically plausible learning algorithm, called LEABRA ('Local, Error-driven and Associative, Biologically Realistic Algorithm'), it was shown that cognates were learned faster than words without a form-similar translation in another language, whereas false friends were learned as slow or somewhat slower than such control words. The simulations suggest that the inherent properties of cognates (form and

meaning overlap) and false friends (form overlap but no meaning overlap) do not only affect how these items are processed after solid learning, but that they are already different during the learning process itself.

Interactions at the Sentence Level

A number of studies at the *sentence* level indicate that, like their lexicons, the grammars of different languages are not stored independently but together. This has, for example, been investigated in sentence interpretation tasks, in which bilinguals and second-language learners are confronted with a simple sentence (e.g., 'the boy kissed the girl' or 'the man touched the stone'), where they have to indicate which of the sentence's arguments is 'doing the action.' Many studies have found that second-language learners are strongly influenced by L1 processing preferences while performing the sentence interpretation task in their L2 (e.g., Gass, 1987; Harrington, 1987; Liu et al., 1992; McDonald, 1987). However, with increasing proficiency in the L2, L2 learners have been found to gradually develop more target-language-like sentence interpretation strategies (e.g., McDonald and Heilenman, 1992). This does not mean, however, that cross-language interactions at the sentence level are absent in more proficient L2 learners. Indeed, in learners with a high proficiency in both languages, both the L1 and the L2 have been found to mutually influence both L1 and L2 sentence interpretation (e.g., Liu et al., 1992).

The sentence interpretation effects are often accounted for in terms of the Competition Model (e.g., MacWhinney and Bates, 1989; later also termed Unified Competition Model; e.g., MacWhinney, 2005, 2008; 2012). The basic tenet of this model is that languages consist of multiple mappings from linguistic form to communicative function (i.e., *cues*, such as word order, case marking, or subject–verb agreement) that interact and/or compete with each other to come to an interpretation of a sentence. These cues are not only assumed to interact with each other *within* a language, however, but also *between* languages, leading to cross-language interaction of language-specific form–function mappings. Similar to the earlier-discussed RHM, the competition model holds that these form–function mappings are stronger in the L1 than in the L2 in beginning L2 learners, such that L2 sentence processing is initially based on L1 processing strategies. In more experienced L2 learners, form–function mappings in the L2 sentence interpretation will have become stronger, making L2 sentence processing less parasitic on the L1 (and sometimes leading to mutual influences between the L1 and L2).

Cross-language interactions at the sentence level have also been observed in the form of *cross-language syntactic priming* (e.g., Bernolet et al., 2012; Loebell and Bock, 2003; Hartsuiker et al., 2004; Weber and Indefrey, 2009). Cross-language syntactic priming is the process in which a bilingual's syntactic processing of an utterance is influenced by the syntactic structure of a recently processed utterance *in a different language*. Hartsuiker et al. (2004) asked pairs of Spanish–English participants to describe cards depicting transitive events to each other in a dialogue game. One of the participants was a confederate, who produced utterances according to a prescribed format. It was found that the 'real' participants tended to use similar sentence constructions as the confederate, even though the confederate used Spanish and the real participants used English. Similar findings of cross-language syntactic priming have now been replicated across different languages, from L1 to L2 and from L2 to L1, in different syntactic structures and constituents, using different task varieties (see, e.g., Hartsuiker and Pickering, 2008, for a review).

It is interesting to note that, like in bilingual word-processing studies, cross-language interaction in sentence production is influenced by relative language proficiency. Schoonbaertet al. (2007) found, for example, that cross-language syntactic priming in Flemish learners of English occurred both from L1 to L2 and from L2 to L1, but that enhanced priming due to lexical repetition between prime and target (i.e., the lexical boost effect) was only present from L1 to L2; not from L2 to L1. Similarly, Kootstra and Doedens (submitted) found in Dutch learners of English that long-lasting effects of cross-language syntactic priming were only present from L1 to L2 and not from L2 to L1. They also found that L1 structural preferences associated with specific verbs (verb alternation bias) influenced L2 syntactic choices in picture descriptions, but L2 structural preferences influenced L1 syntactic choices to a lesser extent. Finally, Kootstraet al. (2012) found that lexical priming in the production of bilingual sentences was stronger in high-proficient bilinguals than in low-proficient bilinguals.

The cross-language syntactic priming studies are often accounted for in terms of a model in which words (lexical representations) and sentence structures (syntactic representations) are represented in a processing system that is shared for both languages (e.g., Hartsuiker et al., 2004). This shared system is exactly what makes cross-language syntactic priming possible: when a syntactic representation has just been used in Language A, it is still relatively strongly activated when a next sentence is produced in Language B, thus increasing the likelihood that this structure is used again. To account for the effects of relative language proficiency, a similar assumption is made as in the RHM and in the competition model, namely that the connections between concepts and linguistic forms are stronger in the (stronger) L1 than in the (weaker) L2. Therefore, the influence of L1 on L2 processing will be stronger than vice versa.

An interesting point with respect to SLA is that syntactic priming does not only provide a methodological tool to investigate cross-language interactions in bilingual sentence production, but may also serve as a mechanism underlying the acquisition of syntax. That is, priming of syntactic structure can be seen as reactivation and strengthening of a just used syntactic representation in memory; when this takes place frequently and consistently in the target language (e.g., the L2), priming could indeed result in the gradual acquisition of target-language form-to-meaning mappings (see, e.g., Chang et al., 2006). This potentially facilitating role of (within-language) syntactic priming for language acquisition has recently been applied and empirically confirmed in the context of L2 learning (e.g., McDonough, 2006; Trofimovich and McDonough, 2011; Shin and Christianson, 2012). Indeed, it has even been found that L2 syntactic priming can override negative effects of L1 transfer (Nitschke et al., 2010). Thus, L2 syntactic priming could serve as an important mechanism of L2 acquisition, in which L2

learners learn to associate L2 syntactic structures with their meanings on the basis of recent (and continuous) exposure to the L2. Based on this, the mechanism of priming is now also investigated as a potential technique for L2 teaching in educational settings (see Trofimovich and McDonough, 2011, for examples).

In all, the discussed studies on lexical and syntactic cross-language interactions reveal that both language comprehension and production in second-language learners and bilinguals is based on a processing system that is shared for both languages and prone to cross-language interactions. We have also shown that these cross-language effects are not only dependent on linguistic factors such as cognate status or language-specific form–function mappings, but also on learner characteristics, such as relative language proficiency. This shows that the nature of cross-language interactions in second-language learners is dynamic in itself. The dynamics of second-language learning are the topic of the next section.

The Dynamics of Language Learning across the Life Span

It is often mentioned that a child can learn a second language more quickly than an adult. Clearly, the brain of a child is still under development and relatively 'empty,' whereas that of an adult is more stabilized and filled with knowledge. There are many differences in the learning situations of both populations. Young L2 learners feel an urgent need to communicate, they are exposed more frequently to the L2, they are not afraid to make mistakes, they use concrete language about the here and now, and their memory/brain is plastic and not stowed with knowledge. However, older and later L2 learners may profit from other advantages: they already know about the world the language is referring to, they have well-developed cognitive abilities, reading abilities, learning skills and study skills, and a complete L1 language system (to which they can relate their new system). In this context, we should also consider the amount of time that someone can spend on L2 learning, whether that person already knows other languages, whether the new language is similar to the old one(s), whether the learner is a man or a woman, whether someone is talented for language or not, and what the motivation of the person is in acquiring the new language (e.g., for a living or for life).

A general observation is that the sensitivity to learn a second language becomes less when a person ages. However, it appears that talking about a strict 'critical period' for L2 learning is a bit too strong. Sensitivity does not decline catastrophically after puberty, but gradually, and learning another language at a later age is still possible.

Babies initially are sensitive to *phoneme distinctions* that exist in all different languages. Already after half a year their perception of nonnative phonemic contrasts declines and that of specific native contrasts increases (e.g., Werker et al., 1981; Kuhl, 2004). The older they get, the more difficult it becomes to learn to master the sounds of other languages. However, this development is not unitary but depends on specific acoustic/articulatory sound characteristics involved (Rivera-Gaxiola et al., 2005). Nevertheless, with motivation and effort, a very high level of pronunciation can still be reached also in later stages of life (Bongaerts et al., 1997). It appears to be somewhat easier to learn the *grammar* of an FL earlier in life, whereas the acquisition of vocabulary is less sensitive to age of acquisition (Ullman, 2001). The explanation of Ullman for this is in terms of two types of memory. The first type of memory stores facts and events (declarative memory); this is important for our 'dictionary.' The second type of memory is involved in learning and actions (procedural memory) and is important for the acquisition of sequences. Grammar is concerned with word order and the learning of grammar is therefore subject to the second type of memory. This second type of memory would be sensitive to hormonal changes, and it would be somewhat more effective before rather than after puberty. A consequence of this view is that one learns a language somewhat differently at a later age relative to an earlier age: somewhat less 'intuitively' and with a more conscious desire to derive rules. Seen from this developmental perspective, it can be understood why (late) L2 learners are betrayed as nonnative, especially in terms of their pronunciation and grammar (see, e.g., Diaz et al., 2008).

A 'real-life' event that underlines this point was described by Monica Schmid (e.g., 2012). At the brink of the Second World War, in the years 1938–39, a very large number of Jewish children were transferred from Germany to England by charity organizations to prevent their persecution. This transfer has been called the '*Kindertransport*'. The age of the children varied from very young (2 years) to post-puberty (17 years). Because the children ended up in foster parent families, they often lost all opportunities to speak German. In many cases, they were reluctant to do so anyway. However, sometimes the children escaped with other family members, and as a consequence some German communication was taking place. Since the 1990s, the testimonies of the children have been recorded in extensive archives. Using these, one can analyze the precise role played by the age at which the children acquired the FL and the moment at which they started to forget their mother tongue. Schmid showed that the age at which the children left Germany was more important for the quality of the remaining German, than whether they were transferred to England with other family members. It appeared that their language problems were especially concerned with the activation and access to their German lexicon, rather than a loss of their linguistic knowledge or the replacement of their first language by a second one.

There are many other studies on how age of acquisition and age of initial exposure (or age of arrival in a foreign country) affect the learning of a second language. In view of space limitations, we will consider only two of the most known of these. Johnson and Newport (1989) used a grammatical judgment task to test the English proficiency of 46 native Korean and Chinese speakers, who arrived in the United States between age 3 and 39, on a variety of English syntactic constructions, including past tense, plural, third person singular, present progressive, and determiners. There was a clear performance advantage for earlier arrivals relative to later arrivals that was linearly related to age of arrival up to puberty (set at age 16), but variable and unrelated to age of arrival after puberty. This effect appeared on all tested grammatical structures, although there were considerable performance differences between

constructions and individuals as well (for follow-up studies see Birdsong and Molis, 2001; Liu et al., 1992).

In an EEG study (Electroencephalography, i.e., recording of neural activity across the scalp), Weber-Fox and Neville (1996) investigated how the syntactic and semantic processing of Chinese learners of English changed depending on the age at which the learners were first exposed to English. Understandably, the learners' self-ratings for reading, listening, speaking, and writing in their new language decreased when they were older upon first exposure; in contrast, their first-language ratings increased. Similarly, their performance accuracy on sentences that had semantic or syntactic anomalies decreased with age of first exposure. Altered patterns of semantic and syntactic processing depending on age of first exposure were also visible in their EEG. For semantic processing, there were altered behavioral patterns and a latency shift in the relevant EEG markers with an age of first exposure higher than 11 years. For syntactic processing, differences in both types of measure were visible already at a much earlier delay (age of exposure 8 years or less). A conclusion is that especially syntactic processes appear to be qualitatively and quantitatively different in late L2 learners, whereas semantic processes often differ quantitatively (also see Ardal et al., 1990; Kroll and Dussias, 2004; Ojima et al., 2005).

Late Child Learners of a Second Language

In addition to the age factor, the dynamics of second-language learning have also been studied by considering the first stages of late second-language learning in children and in adults. With respect to child L2 learners, Poarch and van Hell (2012) considered the production performance of German children who had just begun to acquire English as a second language in school at ages 5–8. Three groups of young participants were tested: German learners of English, German–English bilinguals, and German–English–Language X trilinguals (where Language X was a 'dual L1'). All three groups were found to exhibit a cognate facilitation effect in picture naming in their nondominant language English. The more balanced bilinguals and trilinguals also showed a smaller facilitation effect in their dominant language, German. These findings indicate that the language processing system is not only shared for both languages in adults, but also in young children.

Two word-level studies by Brenders and colleagues considered the L2 comprehension performance of Dutch children aged 9–11 years who had just started to acquire English as a second language in primary school. The first study (Brenders et al., 2011) reported a cognate facilitation effect in L2 lexical decision for L2 learners even in the early stages. Interestingly, adding false friends to the stimulus list turned this facilitation into inhibition. The explanation given by the authors was that the presence of false friends in the stimulus list makes the young participants aware of potential problems in mapping active items to the 'yes' response (remember that false friends and cognates activate their readings in both languages of a bilingual). Thus, responses to cognates suffered because suddenly their membership of the nontarget language was considered to be relevant. In the second study, Brenders et al. (in revision) used an L2 to L1 word translation task. Combining reaction times (RTs) and event-related potentials, they found that L2 words activated their conceptual representations early in the learning process, as indicated by N400 effects already in fifth-graders with only 5 months of English instruction (the N400 is a marker in the EEG that is sensitive to lexical and semantic integration). See also Poarch et al. (2014), for a similar study with RTs. Apparently, already at an early stage Dutch, beginning L2 learners of English make use of the L2 word form to concept mappings to access the L2 word meaning without mediation of the L1 word. This is in contradiction with the predictions of the RHM (see also Altarriba and Mathis, 1997; Cheng and Leung, 1989; Kroll et al., 2002; Brenders, 2012, gives a full review).

One suggestion to resolve this issue is that differences in obtained results are due to the different teaching methods applied to L2 learning, because they pay more or less attention to meaning aspects. Comesaña et al. (2009) studied the creation of L2 words' conceptual representations in children, examining the efficacy of two L2 word-learning methods: L2–L1 word association learning and L2-picture association learning. In a translation recognition task (Experiment 2), Spanish–Basque learners, aged 10–11 years, saw semantically related pairs of words from different languages and unrelated word pairs. They had to say whether the second word in the pair was a translation of the first one. A semantic interference effect (for pairs of words where prime and target were not translations but were semantically associated, like 'table' and 'chair') was already found after only one vocabulary learning session. Because the L2 picture method produced a larger semantic interference effect than the L2–L1 method, this suggests that the speed of linking L2 word forms to semantic representations may depend on the vocabulary training method. Furthermore, it is important to point out that word translation recognition is a relatively slow task that may not be optimally suited to address the issue of fast word form to concept mappings (also see Dijkstra and Rekké, 2010).

Late Adult Learners of a Second Language

The very first stages of second-language learning have also been investigated in *adults*.

With respect to adults, studies have shown that during the first encounters with an FL, many aspects of the new language are quickly picked up. For instance, Gullberg et al. (2010, 2012) showed that already after watching 7 min of a Chinese weather forecast, the viewers had acquired a considerable amount of information about the Chinese phonology of word forms and after 15 min they had already assigned meanings to particular words.

Researchers have extended their studies on this topic by considering electrophysiological (EEG) and magnetic resonance imaging techniques (e.g., Osterhout et al., 2006; Morgan-Short et al., 2012; Weber et al., in preparation). Whereas many of these studies are concerned with grammar learning, McLaughlin et al. (2004) determined after how much FL exposure a learner's EEG responses to existing FL words and pronounceable pseudowords (nonwords) started to resemble those of a native speaker. Participants were English-speaking university students in their first year of classroom instruction in French and a control group without

any French instruction. The learners performed a lexical decision task on all materials. After only 14 h of FL instruction, the pseudowords already elicited a larger N400 EEG response than the existing words. Interestingly, the effect occurred even though learners performed at chance level in a French lexical decision task. Thus, at a neurocognitive level, the learners became quickly sensitive to FL word forms, even when there was no clear benefit at the decision level yet. After about 60 h of FL instruction, smaller N400's arose to words preceded by a related than by unrelated word, reflecting sensitivity to word meaning. Finally, after about 140 h of FL instruction, the word/nonword and relatedness differences approximated that of native English or French speakers in amplitude, even though the learners' explicit word/nonword judgments remained very poor.

In all, these EEG data suggest that adult learners rapidly integrate lexical information in their mental lexicon (about word form, and in a later stage about word meaning). These effects are not always found in standard behavioral assessments (e.g., RTs), implying that the EEG might more sensitively reflect aspects of implicit learning and continuous lexical change.

Recently, two longitudinal projects at Radboud University Nijmegen, with the acronyms VILLA and SLANG, have begun to investigate the very first stages of second-language learning in adults from a perspective that is somewhat different from that taken by McLaughlin, Osterhout, and colleagues. The project called 'Varieties of Initial Learners in Language Acquisition' (VILLA) investigates the very first phases of FL acquisition in children and adults under controlled input conditions (for its predecessor, see Gullberg et al., 2010, 2012). In VILLA, adult and child learners with different native languages (Dutch, English, French, German, Italian) were exposed to 20 h of input in a new language (Polish) with which they were completely unfamiliar. The language input across sessions was similar to those in standard FL courses, but learning was held constant under relatively natural and interactive exposure conditions. The learners' performance was examined over a period of 2 weeks with respect to a diversity of linguistic levels (phonology, lexicon, morphosyntax, and semantics/pragmatics) in order to find out more about the most elementary stages of linguistic organization resulting from the teaching. Off-line language aptitude tests and on line psycholinguistic experiments were administered to the learners before and after classroom exposure at regular time intervals during the duration of the project.

Figures 1 and 2 illustrate some of the first results of the project. In this part of the project, participants performed a Polish lexical decision task every 2 days, i.e., five times in the 2-week learning period. The stimuli in the task were Polish words and nonwords with different characteristics. The Polish words consisted of noncognates or cognates with the native language of the participants (e.g., Polish 'MUSEUM' is

Figure 1 (a)–(c) Cumulative distribution functions for words with a high and a low frequency of presentation at the beginning of the Polish course, after 3 h, and after 6 h of input. More frequent presentation results in faster response times.

Figure 2 (a)–(c) Cumulative distribution functions for cognate and noncognate words at the beginning of the Polish course, after 3 h, and after 6 h of input. Cognates result in faster response times than noncognates.

phonologically very similar to 'MUSEUM' in Dutch) with a high or low frequency of presentation in the study (the exact number can be derived from a transcription of the teacher's speech). In Figure 1(a)–(c), it can be seen that from early on, words were processed faster and more accurately when their frequency of presentation was higher. From Figure 2(a)–(c), it is clear that participants quickly became sensitive to whether the item was a cognate between Polish and the native language (in this case, Dutch) or not. They very quickly noticed the cross-linguistic similarities in word form and meaning and used these to speed up their response times.

During the 20-h course, a morphosyntactic comprehension task was administered twice. This task was designed to investigate the development of nominal morphological marking and word order in the acquisition of the Polish morphosyntactic system. Polish is a highly inflected language with seven cases that allows relatively flexible word order. Two of the learner groups were native speakers of Dutch or French without any knowledge of Polish or another Slavic language. Dutch has much less case marking than Polish and also has fairly flexible word order. French has no case marking on the noun and has strict word order. For each source language, there were two groups of learners; one received 'meaning-based input,' in which the instructor provided no explicit information about grammar, and the other received 'form-based input.' in which the instructor highlighted aspects of morphosyntax. Results on the comprehension task, administered after 9 h and again after 13 h of Polish instruction, reveal a role of source language in that French and Dutch learners differed in their processing of case marking and word order. With regard to the type of input, no significant difference was found between the meaning-based input groups (French and Dutch) and the form-based input groups (French and Dutch) after 9 h of exposure to Polish. After 13 h, however, the French learners who received meaning-based input performed better than those who received form-based input. In contrast, the Dutch learners who received form-based input performed better than those who received meaning-based input. Analyses of individual differences tests revealed that individual variability may have played a role as well.

The VILLA project focused on behavioral aspects of FL learning during the first 2 weeks of exposure in a classroom-like setting (see Rast, 2008, for a theoretical background). However, longer lasting studies (Xiang et al., 2012) indicate that important further developments take place in the weeks and months after this initial learning stage. Furthermore, as the studies by Osterhout et al. (2006) and by Brenders et al. (in revision) suggest, EEG data might pick up early changes in the language processing system that behavioral assessments (i.e., latencies, error rates) are not yet sensitive to. For these reasons, another longitudinal project, called SLANG (for Second Language Acquisition), was started in which young adult German learners of Dutch were followed for a period of nearly half a year, with regular collection of their behavioral and electrophysiological responses to Dutch words of different types and enriched by off-line test data. Already at a very early stage of learning, words in the new language were found to be processed up to semantic and affective (emotion) levels. With respect to emotion words in the new language, the learners already responded differently after only 1–2 weeks of language learning (Middelburg et al., in preparation; Sianipar et al., in preparation). Positive words appeared to have a special status in the earliest stages of learning: RTs to these words were faster, fewer errors were made on them, and they displayed a more positive-going Late Positive Complex (LPC: an EEG marker at 600–800 ms after the stimulus event, often found in emotion word processing). Arousal of the words affected the EEG indirectly via interaction with the valence response. Valence itself played a role in L2 emotion word processing from the earliest stages of SLA onwards. In the course of half a year of L2 learning in the classroom and submerged in society, the results approached those of a native control group, but were still different at the end.

Conclusion and Future Developments

In this contribution, we discussed two core aspects of second-language acquisition, namely that it is (1) interactive and (2) dynamic. Of course, given the multifacetedness of the field of second-language acquisition, there are many more factors and notions that play a role in second-language acquisition and could have been discussed. This was not possible within the limited space of this contribution, however (see, e.g., Gass and Mackey, 2012; Robinson, 2013, for elaborate overviews of the field of second-language acquisition). Instead, we focused on the role of a number of central language-related and learner-related factors in the comprehension, production, and acquisition of a second language, and explained second-language acquisition and use from a psycholinguistic perspective on language processing.

In addition to these core issues, there are a number of developments that may lead to new insights in the future. One of these is the application of laboratory-based research techniques in schools. Brenders et al. (in revision), for instance, used EEG measurements in a study on bilingual processing in primary school children by driving a minivan equipped with EEG recording hardware to primary schools. This made it possible to test the neurocognitive mechanisms of second-language learning in primary school children, which would otherwise be much more effortful to investigate. Another development is the study of intraindividual variation in the SLA process. De Bot and Lowie (2010; see also De Bot et al., 2005), for instance, studied stability of lexical processing over time in single second-language learners and found interesting patterns of variation in these learners. This focus on variation over time can in the end lead to more insight into the dynamics of the language learning process. A final development that we name here concerns the application of insights from research on second-language acquisition in educational contexts. For instance, research has made it clear that the teaching methods used play an important role in the ways new information is integrated in the language systems that are already present in the FL learner (Comesaña et al., 2009). In addition, the insight that early learning of an FL is typically less effortful than late learning and may even lead to more general cognitive and academic advantages has led to the development that many schools in the Netherlands have now

implemented (partly) bilingual programs (mostly Dutch–English), sometimes already starting in kindergarten. Studies are now performed to investigate the circumstances in which these programs are indeed beneficial for children's linguistic, academic, and overall cognitive development.

In this article, we took a psycholinguistic perspective to show that second-language learning results from complex interactions on multiple dimensions. It is exciting to see that increased communication between researchers from different backgrounds, teachers, interpreters, language learners, and others slowly but surely results in a better understanding of this important human skill.

Abstract

This article presents a general introduction to second language acquisition (SLA) as an academic discipline investigating how a second language is learned. It first defines and distinguishes between some terminologies commonly used in the field. It then reviews the influential theories proposed to account for SLA and examines the major factors that may affect acquisition. In addition, it predicts the future trends of SLA research in the twenty-first century. Lastly, the chapter concludes with a summary of the discussions presented in the previous sections.

Introduction

The topic of second language learning and teaching has been intriguing scholars since ancient times, but second language acquisition (SLA) as an independent research discipline is quite new, having started in the 1960s. Unlike their predecessors who focused on pedagogy, SLA researchers are interested in the nature and process of learning. They seek answers to such questions as how a second language (L2) is acquired, and what makes individuals learn at different rates and achieve different degrees of success.

Since its very beginning, SLA has been an interdisciplinary field. To uncover and understand the mechanism of acquisition, scholars draw upon theories and findings from a variety of fields, including linguistics, psychology, education, sociology, anthropology, among others. SLA is a subject worthy of serious and scientific exploration for a number of reasons. Most importantly, of course, it can help us understand the process of second language learning. It can also benefit second language teaching, e.g., with respect to curriculum design and teaching methodology. In addition, it may shed lights on other related disciplines, especially disciplines which it has drawn knowledge from.

Definitions

The term 'second language acquisition' in a broad sense refers to the learning of a nonnative language after the first language (L1) (i.e., the native language) has been learned, either in a naturalistic setting or in a formal classroom setting. Before we go into detail, it is necessary to clarify some terms commonly used in the filed.

- Second language versus foreign language

The distinction between 'second language' and 'foreign language' is related to the function of the language in concern in the larger sociocultural setting where learning takes place. A second language is a language that plays important social and institutional functions in a country although it may not be the native language (NL) of the dominant population, for example, English in India and Singapore. In the case of language learning, a second language is a nonnative language to which the learner has natural exposure, as in the case of the learning of English by many immigrants in the United States.

A foreign language, on the other hand, is a language that is not the native language of the majority of the population, nor is it widely used as a medium of communication in the country. Instead, it is only used for speaking to foreigners or for reading written materials. It is usually learned as a subject in school. A typical example is the learning of English by a Japanese speaker in Japan.

- Second versus third language acquisition

Although SLA often refers to the learning of any language other than L1, in recent decades there has emerged an area of research focusing on the learning of the third, or even the fourth, language, which is known as multilingual acquisition. One major issue studied in this field is the relationship between the third (or fourth) language and other languages the learner has learned previously, e.g., L1 or L2 (see Gass and Selinker, 2008, pp. 21–23).

- Acquisition versus learning

SLA researchers sometimes distinguish between 'acquisition' and 'learning.' Acquisition refers to the learning of a nonnative language in a naturalistic environment (e.g., when a Russian speaker learns French in France). Learning, in contrast, refers to the learning of a nonnative language in an environment in which that language is not natively spoken (e.g., when a Russian speaker learns English in Russia). This distinction correlates with the distinction between 'second' versus 'foreign' language as discussed above, and hence the terms 'second language acquisition' and 'foreign language learning' are used with distinctions on a similar dimension.

Unless noted otherwise, this article follows the practice of most SLA researchers, without making the fine distinctions introduced above (e.g., Larsen-Freeman and Long, 1991; Ellis, 1994; Gass and Selinker, 2008). The term 'second language acquisition' is used to refer to the learning of any nonnative language, regardless of the sociocultural nature of the learning environment (second vs foreign) and the order in which the language is learned (second vs third, or fourth). Nevertheless, it should be pointed out that the learning environment exerts significant influences on SLA. For this reason, SLA in the classroom is sometimes discussed separately under various titles, e.g., 'instructed second language acquisition' (Larsen-Freeman

 http://dx.doi.org/10.1016/B978-0-08-097086-8.92096-8

and Long, 1991), 'classroom second language acquisition' (Ellis, 1994), and 'instructed second language learning' (Gass and Selinker, 2008).

How Is a Second Language Acquired: Theories of SLA

A variety of theoretical frameworks have been proposed in the field of SLA to describe and account for the L2 learning process and "learners' underlying knowledge" (Ellis, 1994, p. 13) of the target language (TL). Some theories focus on the explanation of L2 output data, and some on formulating models of the learning process. This section will introduce the major SLA theories.

The Behaviorist Approach

The earliest approach to SLA is Contrastive Analysis (CA) developing under the influence of psychological theories, especially behaviorism prevailing in the 1950s and 1960s.

- Contrastive Analysis

During the 1940s and 1950s, researchers interested in improving language pedagogy believed that contrastive analyses of the learners' native language and the target language would reveal what structures would be easy to learn and what would be difficult. This led to the proposal of the Contrastive Analysis Hypothesis (CAH) by Lado (1957), who argues that L2 learners tend to transfer L1 forms to L2 use and that L2 errors could be predicted through systematic comparisons between L1 and L2 (cited in Larsen-Freeman and Long, 1991, pp. 52–56; Gass and Selinker, 2008, pp. 89–102). Similar structures will be easy to acquire due to positive transfer, whereas different ones will be difficult and cause negative transfer or interference (cf Flege, 1992, 1995, cited in Major, 2001, pp. 38–41, for a different view).

L1 transfer is especially powerful at the beginning stage of L2 acquisition, and it may occur at all levels of linguistic structure, from phonology, morphology, lexicon, syntax, semantics, to discourse and cultural norms. Some examples of L2 errors due to negative L1 transfer are given in **Table 1**, where L1 is Mandarin Chinese and L2 is English. For example, in the native language (Mandarin), a same word 'wen ti' can be used to mean either a question or a problem. In the target language (English), however, 'question' and 'problem' are two words of different meanings. In this case, one single form in L1 corresponds to two distinct items in L2, and hence an error occurs when the learner uses one of the two L2 words (e.g., 'question') to refer to the other (e.g., 'problem').

CAH developed at a time when the behaviorist school of psychology prevailed. According to behaviorism, learning is a process of habit formation, during which the learner applies his previously learned skills to the learning of a new one. New habits are developed through repeated imitation and intensive practice. When learning a second language, one needs to overcome L1 habits in order to acquire new habits in L2.

CAH was soon challenged by findings from empirical studies. For instance, some errors predicted by CA do not actually occur. In addition, some errors that actually occur are not predicted and hence cannot be attributed to L1 transfer. Furthermore, CA, at least in its earlier forms, cannot predict the relative difficulty of L2 structures, that is, what areas cause more difficulties than others (Major, 2001, p. 34). Despite these problems, it is undeniable that L1 transfer is an important factor influencing L2 learning. A weak version of CAH using CA to explain (rather than to predict) some L2 errors, is still commonly practiced today.

Cognitive Approaches

Some other approaches to examining the nature of the L2 learning process are based on cognitive perspectives. In such frameworks, language learning is seen as a process in which learners constantly form hypotheses by use of their own cognitive abilities. Three theories can be grouped under this category, the Error Analysis Hypothesis, the Universal Grammar (UG) Model and the Monitor Model.

- Error Analysis

In the late 1960 and 1970s, researchers started to view L2 errors from a new perspective. Corder (1967) expounds the importance of errors, arguing that errors are systematic and serve as significant evidence of the learner's language system (see reviews in Larsen-Freeman and Long, 1991, p. 58; Gass and Selinker, 2008, p. 102). Selinker (1972) introduces the term 'Interlanguage' (IL) to refer to the L2 learner's language system or grammar during the course of learning (cited in Ellis, 1994, p. 44). In his view, the learner actively constructs grammars based on the limited input he has received. These grammars constitute a continuum, with L1 at one end and L2 at the other (Ellis, 1994, pp. 350–356).

Interest in learner errors triggers a series of studies on the classification of IL errors. Major types of errors are interlingual errors – errors caused by NL transfer, and intralingual

Table 1 Examples of L1 transfer errors

	L1 (Mandarin)	*L2 (English)*	*L2 output*	*Error example*
Phonology	Lack of stop codas	Existence of stop codas	Vowel insertion	*/li:də/ for 'lead' /li:d/
Morphology	Isolating	Inflectional	Omission of inflections	*He paint the house last week. (*'Paint' for 'painted')
Syntax	Wh-in-situ	Overt wh-movement	Wh-in-situ	*You go where? (For 'where do you go?')
Semantics	One word (e.g., 'wen ti')	Two words (e.g., 'question,' 'problem')	One word (e.g., 'question')	*Water pollution is a serious question. (*'Question' for 'problem')
Paragraph development	Nonlinear	Linear	Nonlinear	e.g., Kaplan (1966)

Note: The asterisk '*' indicates an ungrammatical structure.

errors – errors independent of NL (e.g., overgeneralization and simplification errors). Other types include communication-based errors (i.e., errors resulting from a speaker's use of communicative strategies) and induced errors (i.e., errors due to training) (see discussions in Larsen-Freeman and Long, 1991, pp. 58–60; Ellis, 1994, pp. 57–63).

Error analysis (EA) replaced CA as a dominant approach to SLA research in the 1970s. As the term denotes, it focuses on the analysis of learners' errors. Unlike CA comparing L1 and L2, EA studies the learner's IL by examining the differences between the IL and L2. It was the first theory focused on serious investigations of learner language (Ellis, 1994, pp. 68–70). It broadened the scope of error sources, taking into consideration not just L1 transfer but also others (e.g., overgeneralization or training).

EA has a number of limitations. Firstly, it is not always easy to identify the type and source of an error. For instance, a deviant English form such as "She *arrive* late yesterday" produced by a Mandarin Chinese speaker learning English may be considered either as a morphological error (with lack of the past tense marker '-ed') or as a pronunciation error (with deletion of the final consonant /d/ in 'arrived'); it can be either a transfer error since Mandarin (L1) lacks inflectional morphology or a developmental error that a native English-speaking child also makes. Secondly, EA has a limited view on L2 acquisition by only looking at errors that actually occur, without considering the whole picture of the learner's behavior, e.g., the strategies to avoid using a difficult form and hence make fewer errors (see discussions in Larsen-Freeman and Long, 1991, pp. 61–62; Gass and Selinker, 2008, pp. 104–110).

- UG Model

The Universal Grammar (UG) (Chomsky, 1965, cited in White, 2003, pp. 2–4) assumes that the mental grammar an adult has of his or her native language consists of universal principles and variable settings of parameters. The principles are the same in all human languages, and parameter settings vary across languages. In language acquisition, input triggers the setting of parameters in the particular language being learned.

Since the 1980s, some researchers have started to explore the application of UG to SLA research. Major questions pursued along this line include whether UG remains accessible in SLA and how universals affect SLA. For instance, White (2003) studies the extent to which L2 acquisition is constrained by universal principles, arguing that UG constraints do function in SLA. She outlines different possibilities for the initial state of L2 learning, with different degrees of L1 transfer. For instance, in the case of full transfer (Schwartz and Sprouse, 1994, 1996, cited in White, 2003, pp. 61–68), L1 grammar constitutes the initial state. On the contrary, a full access situation (Epstein et al., 1996, 1998, cited in White, 2003, pp. 88–95) consists entirely of UG in the initial state.

However, L1 acquisition and L2 learning are different in many ways, which raises caution about the strong claims of access to UG in SLA. For instance, L2 learning starts out with the leaner having already formed a set of skills and strategies in L1, but this is not the case in L1 acquisition. L2 learners also have different motivations from children acquiring their NL. In addition, the sociocultural setting of SLA is much more complex than that of children's L1 acquisition. These differences present challenges to the arguments of UG availability in SLA.

- The Monitor Model

The Monitor Model was formulated by Krashen in the 1970s and 1980s. It seeks to account for the natural order of acquisition on the one hand and the disturbances observed in the order in specific performance tasks on the other.

Krashen (1976) distinguishes between two knowledge systems governing L2 performance (cited in Larsen-Freeman and Long, 1991, pp. 240–241). One is the acquired system, consisting of subconscious knowledge similar to what children have for native language acquisition. The other is the learned system, which results from formal instruction and serves to monitor performance (output) consciously. The two systems are completely separate, each accounting for a different aspect of performance. The natural order in which TL rules are acquired embodies the acquired system, whereas disturbances in the order result from conscious monitoring by the learned system.

The Monitor Model contains five hypotheses, two of which state crucial conditions necessary for SLA. One is the Input Hypothesis, which postulates that the learner acquires a second language through comprehensible input and that progress in learning is achieved when the input is one level above the current stage of the learner's interlanguage development (see discussions in Larsen-Freeman and Long, 1991, pp. 242–243; Gass and Selinker, 2008, pp. 309–310). The other is the Affective Filter Hypothesis, which posits that affective factors like motivation and self-confidence promote acquisition when the filter is low (e.g., when the learner is highly motivated and confident in learning) (see reviews in Larsen-Freeman and Long, 1991, pp. 243–244; Gass and Selinker, 2008, pp. 402–403).

Various components of the Monitor Model have encountered criticisms (Larsen-Freeman and Long, 1991, pp. 245–249). For instance, the model provides no measures to distinguish between acquisition and learning. Furthermore, the Input Hypothesis and the function of the affective filer cannot be easily tested. Nevertheless, this theory motivates new thoughts about the relationship between various factors in L2 acquisition and about the issues to consider in designing language instruction materials.

Interactional Approaches

Interactional approaches take into consideration the interactional nature and the communicative functions of language to account for the mechanism of second language learning.

- Conversation Analysis

Conversation Analysis, a subarea of discourse analysis, examines language learning as situated in the social interaction that the learner participates in. It recognizes that language cannot be understood in isolation from social contexts and argues that changes in the structure of the interaction discourse evidence learning (see review in Gass and Selinker, 2008, pp. 281–283). In this framework, the conversation between the L2 learner and his or her interlocutor constitutes an important source of language acquisition, serving a variety of functions, e.g., to provide feedback and corrections, to encourage participation and to negotiate meaning. For instance, Hatch

(1978) argues that a learner can acquire syntactic structures through conversations or verbal interactions with another person (cited in Larsen-Freeman and Long, 1991, pp. 70–71).

Conversation analysis focuses on the significant role of input and interaction in language learning. By including both form and function, it initiates a number of new directions to investigate SLA, e.g., foreigner talk, contrastive rhetoric, classroom discourse, and speech act analysis (see Larsen-Freeman and Long, 1991, pp. 71–73).

- The Multidimensional Model

The Multidimensional Model developed from the ZISA (Zweitsprachenwerb Italienischer und Spanischer Arbeiter) project conducted in Germany in the 1970s. It was first proposed by Meisel et al. (1981) (cited in Larsen-Freeman and Long, 1991, pp. 270–287; Ellis, 1994, pp. 382–388). Based on the development of word order rules in German as a second language, ZISA researchers propose that two independent dimensions regulate the developmental sequences of the IL. One is the developmental axis, which represents an invariant order of developmental stages. The other is the variation axis, which accounts for the differences among individual learners with respect to whether their orientation toward a learning task is a 'standard' (integrative) one or a 'simplifying' (segregative) one. By using the concept of orientation, the model incorporates the role of social and psychological factors such as motivation and interest in accounting for the learning process.

Although a powerful tool to explain IL development, the Multidimensional Model is not flawless (Larsen-Freeman and Long, 1991, pp. 283–287; Ellis, 1994, pp. 387–388). For instance, it accounts for acquisition in view of the learner's L2 production only, dismissing the interaction between comprehension and production. In addition, it is hard to identify formulaic chunks of language and variational features a priori.

- The Competition Model

The Competition Model (Bates and MacWhinney, 1982, cited in Gass and Selinker, 2008, pp. 221–226) adopts a functional approach to language development. It claims that language forms "are created, governed, constrained, acquired and used in the service of communicative functions" (MacWhinney et al., 1984, cited in Ellis, 1994, p. 374). A form fulfills one or more functions, and a function is realized in one or more forms.

According to this model, languages differ in the strengths of particular form-function mappings. The input provides four types of cues to convey meaning, namely word order, vocabulary, morphology and intonation. Since the human processing system employs only a limited number of information at a time, these different signals compete for processing space. In learning a second language, one needs to figure out which forms are mapped to what functions and what weights these mappings assume in the target language (see Ellis, 1994, pp. 373–378 for more discussions).

Sociocultural Approaches

Sociocultural approaches view language as a social phenomenon and hence language acquisition as crucially determined by sociocultural factors.

- The Acculturation Model

Based on a case of SLA in a naturalistic setting, Schumann (1978a) outlines a range of similarities between an unsuccessful learner's interlanguage and a pidgin, a simplified or reduced form of language used for communication between speakers of different native languages. For instance, both language forms display such characteristics as simple morphology, lack of certain movement rules, and reduced vocabulary (see Larsen-Freeman and Long, 1991, pp. 254–255).

Schumann proposes the Acculturation Model to account for his observations, arguing that naturalistic SLA results from acculturation, i.e., adaptation to or integration into another culture. He claims that "the degree to which a learner acculturates to the target-language group will control the degree to which he acquires the second language" (Schumann, 1978b, p. 34, cited in Larsen-Freeman and Long, 1991, p. 257; Ellis, 1994, p. 230). A high degree of acculturation leads to a greater amount of contact with native speakers of the L2, which facilitates acquisition.

Schumann develops the concepts of social distance and psychological distance to define the extent of acculturation. Each involves a number of factors regulating the relationship between the learner and the target language speaker group. A learner socially and psychologically integrated with the TL group achieves a high degree of acculturation, which further leads to successful L2 acquisition (for detailed discussions, see Larsen-Freeman and Long, 1991, pp. 251–258; Ellis, 1994, pp. 230–233).

While recognizing the significance of social and psychological factors in SLA, the Acculturation Model faces various challenges (Larsen-Freeman and Long, 1991, pp. 258–266; Ellis, 1994, pp. 233–234). For example, it does not specify how those social and psychological factors may regulate the features of the interlanguage. In addition, the factors underlying social distance between the two language groups involved in pidginization (i.e., the superstrate language group and the pidgin group) can be quite different from those involved in SLA (i.e., the individual L2 learner and the native TL speaker group). Moreover, the validity of positing that social factors have a direct effect on L2 acquisition raises doubt since they are generally considered indirect forces.

- Vygotsky's sociocultural theory

Since the 1990s, there has been a revival of interest in Vygotsky's (1978) sociocultural theory (cited in Gass and Selinker, 2008, pp. 283–285), which sees learning as social in nature and language acquisition as situated in social interaction. A central concept of this framework is the Zone of Proximal Development (ZDP), which refers to the distance between a child's actual level of development in terms of problem solving skills and the potential level of skills he is able to reach under the guidance of an adult or through collaboration with a peer who is more capable. ZDP defines a range of developmental levels where a child can learn through accomplishing tasks under guidance.

In the recent decades, a number of studies have employed this approach in SLA research. For instance, it has been shown that learners employ private speech to regulate their language in learning tasks (e.g., Lantolf and Thorne, 2006, 2007, cited in Gass and Selinker, 2008, p. 285).

In short, a great variety of models and approaches have been proposed to explain how a second language is acquired. There are some other models that are not introduced since they are not as extensively pursued as the approaches discussed above. Some examples are Givon's (1979a, 1979b) Functional-Typological theory (see Larsen-Freeman and Long, 1991, pp. 266–270), Eckman's (1977) Markedness Differential Hypothesis (see Gass and Selinker, 2008, pp. 179–182), and the Ontogeny Phylogeny Model (Major, 2001).

What Makes Individuals Learn Differently: Factors Influencing SLA

One phenomenon characteristic of second language learning is that individual learners vary greatly in the rate of learning and the level of achievement. Some learn fast, while others progress slowly. Some succeed in attaining a high proficiency, while others fail despite the enormous efforts they spend.

A plethora of factors have been investigated in the literature (e.g., Larsen-Freeman and Long, 1991; Ellis, 1994; Gass and Selinker, 2008). This section discusses a total of 12 factors, grouped into two categories, namely environmental/setting factors and individual learner factors.

Environmental/Setting Factors

The sociocultural environment and specific setting in which an L2 is learned has crucial influence on the learning process and achievement. It determines how learning is done, what resources are available to learners, what learning objectives are set, how fast learning progresses, and how motivated learners are.

- Naturalistic versus foreign environment

The naturalistic versus foreign nature of the larger sociocultural environment of L2 learning is one of the key factors determining how learning is done and how effectively it is done. Learners in a naturalistic environment acquire the TL through natural exposure in daily communication. They have access to abundant authentic input and plenty opportunities to use the TL, which may boot their motivation to learn, both the motivation to be integrated into the mainstream L2 society and that for practical reasons (e.g., to find a job). With frequent contact with native speakers of the L2, they enjoy advantages in acquiring speaking fluency and listening comprehension. In contrast, learners in a foreign environment get input mainly from classroom instruction, which is limited to interactions with teachers, peer learners and course materials. The input is usually somewhat modified to accommodate students' proficiency level. Learners have restricted opportunities to communicate with native speakers, and hence their motivation to learn is mainly instrumental. The skills they learn tend to focus on reading and writing. These differences related to the nature of the learning environment are summarized in Table 2 below.

Table 2 Differences between SLA in a naturalistic setting and a foreign setting

	Naturalistic	*Foreign*
Means of learning	Natural exposure	Instruction in classroom
Quantity of input	Abundant	Limited
Quality of input	Authentic	Modified
Learner motivation	Integrative and instrumental	Instrumental
Opportunities to use L2	Plenty	Restricted
Primary skills learned	Speaking and listening	Reading and writing

However, it needs to be pointed out that the reality of L2 learning environment is much more complex than a mere division between naturalistic and foreign settings. In a naturalistic setting, a person may attend formal classes to learn an L2 in addition to learning it through daily exposure in the native TL environment. On the other hand, a person learning an L2 in a foreign environment may sometimes create a native-like setting for himself by reading news, watching movies or play games in the TL.

In the long run, the naturalistic and foreign setting may each fare better in certain ways. For instance, learning in a natural L2 environment may lead to a higher level of fluency and communicative competency although not necessarily greater accuracy. A foreign setting, however, may benefit learners with modified input and help them develop a greater awareness of grammar accuracy, but it may lack resources facilitating acquisition of oral fluency and communicative skills.

- Technology

Technology has been an important tool for language learning ever since the mid-twentieth century. A variety of media and devices have been widely used, from conventional ones like radio, cassette recorders, television and video recorders to the current ones like mobile devices, computers and the Internet (Flowerdew and Miller, 2005, pp. 165–183; Godwin-Jones, 2008). For example, there are radio and television programs, audio and video materials, as well as computer software specially designed for language learning and teaching. In present days, it is not uncommon to find language labs and self-access language learning centers equipped with multimedia tools in schools.

Technological advances have brought about dramatic changes to the way L2 learners acquire resources (input) and approach learning tasks. For one thing, they expand the resources and opportunities for learners to get authentic L2 materials. For another, technology offers L2 learners immense freedom in planning and managing learning on their own.

The role of technology is especially significant for SLA in a foreign environment, where learners have limited natural exposure to the TL. For example, today an EFL (English as a foreign language) learner in Korea can have easy access to English news and movies on the Internet and use them to practice reading and listening comprehension anytime he or she wants. If without the aid of technology, the language resources he or she could have might come solely or mostly from the classroom – teachers, course materials and other learners.

Individual Learner Factors

A large body of SLA research looks into the influence of various learner-related factors. Major variables include the following

10: age, sex, affect, aptitude, attitudes, motivation, personality, learning styles, learning strategies, and social distance.

- Age

Studies show that children learn more successfully, but at a lower speed, than adults (see reviews in Larsen-Freeman and Long, 1991, pp. 155–163; Ellis, 1994, pp. 484–494; Major, 2001, pp. 6–12; Gass and Selinker, 2008, pp. 405–416). Young children tend to learn better than adults in the sense that they are more likely to achieve native-like proficiency. This is especially evident in phonology or pronunciation acquisition. However, the opposite tendency is revealed about the rate of acquisition. Older learners learn faster than young learners, especially at the early stage of acquiring morphology and syntax.

This observation of children's advantages over adults in attaining native-like proficiency is supported by the Critical Period Hypothesis (Lenneberg, 1967), which claims that there is a critical period of time, from age 2 to puberty, determining whether native proficiency in a second language can be acquired. For those who start to learn a language, either native or nonnative, after the critical period, it is very hard, or even impossible, for them to attain native-like levels.

- Sex

Females generally enjoy advantages over males in L2 learning (Larsen-Freeman and Long, 1991, p. 204; Ellis, 1994, pp. 202–204). The reason for this may be that women employ more standard and more prestige forms as well as more new forms than do men in using language. When learning a second language, they may be more open to the new input and more likely to eliminate errors, which contribute to their better L2 performance.

- Affect

Affect involves 'feelings or emotional reactions' about L2, the speakers as well as the culture of that language (Gass and Selinker, 2008, p. 398). It includes such specific factors as language/culture shock, stress, and anxiety. Shock and stress may cause problems to language learning. Anxiety can have either negative or positive effects, depending on how intense it is. Anxiety at a moderate or low level is helpful, but at a high level it is detrimental (see Ellis, 1994, pp. 479–483; Gass and Selinker, 2008, pp. 398–403).

- Aptitude

Aptitude is the capability of learning new skills. It is a cognitive ability closely related to, but not identical to, intelligence. Carroll (1981) defines four components of language learning aptitude, namely phonetic coding ability, grammatical sensitivity, rote learning ability for foreign language materials, and inductive language learning ability (cited in Larsen-Freeman and Long, 1991, p. 167; cf Ellis, 1994, pp. 495–496; Gass and Selinker, 2008, p. 418). A well-known instrument to measure aptitude is the Modern Language Aptitude Test (Carroll and Sapon, 1959, cited in Larsen-Freeman and Long, 1991, p. 168; Gass and Selinker, 2008, p. 419).

Aptitude is found to be a strong predictor of L2 performance. It demonstrates positive correlations to the rate of acquisition and achievement in language tests. In addition, it is linked to other factors such as motivation and social class (see discussions in Ellis, 1994, pp. 494–499; Gass and Selinker, 2008, pp. 417–426).

- Attitudes

Attitudes toward the target language and its speakers or community can have an important, although indirect, influence on L2 achievement. According to Gardner (1979), attitudes influence motivation, which in turn influences acquisition (cited in Larsen-Freeman and Long, 1991, p. 175). Generally speaking, positive attitudes toward L2 and its speakers/community facilitate learning.

- Motivation

Motivation is another key factor related to differential achievement in L2 learning. If a learner is motivated, he or she will have an intense interest and be willing to be engaged in learning (Ellis, 1994, pp. 512–514). Two kinds of motivation have been studied extensively, namely integrative and instrumental motivation proposed by Gardner and Lambert (1959, 1972) (cited in Larsen-Freeman and Long, 1991, pp. 172–174). Integrative motivation refers to the learner's desire to be integrated into or identified with the L2 community. Instrumental motivation is related to the usefulness of the language for practical goals, e.g., for career advancement. Both types of motivation serve as strong impetus to learning.

- Personality

Certain personality traits may favor L2 acquisition. Although research results are inconclusive, studies do provide evidence for the correlation between personality and L2 performance. Successful learners are believed to have high self-esteem, be extrovert and willing to take-risks, be tolerant of ambiguity, demonstrate empathy, and have low inhibition (see reviews in Larsen-Freeman and Long, 1991, pp. 184–192; Ellis, 1994, pp. 517–522).

- Learning styles

Learners differ in the styles or modes they prefer to use when approaching learning tasks. Researchers have examined such variables as field-independent/-dependent, reflective/impulsive, aural/visual, and analytic/gestalt styles (Larsen-Freeman and Long, 1991, pp. 192–197). A field–independent person, who is good at abstracting information from the context, learns better than does a field-dependent person, who pays great attention to details in the context. Reflective learners, who tend to think longer and more carefully, make fewer errors than do impulsive learners. Learners who learn by both aural and visual means perform better than do those who employ only a single modality. Furthermore, analytical learners tend to break language forms into smaller components, whereas gestalt learners take a holistic approach, assimilating language in big units and taking more risks in using it.

- Learning strategies

Learning strategies involve both cognitive and behavioral actions. O'Malley and Chamot (1990) define them as "the special thoughts or behaviors that individuals use to help them comprehend, learn, or retain new information" (p. 1) and classify them into three types, i.e., metacognitive, cognitive

and social/affective strategies (p. 43–47). Metacognitive ones are higher order skills used to plan, monitor and evaluate learning activities. Cognitive ones "operate directly on incoming information, manipulating it in ways that enhance learning" (p. 44). Examples are rehearsal, organization, summarization and detection. Finally, social/affective strategies are those learners use to interact with others and control affect (e.g., cooperation and questioning for clarification) (p. 45–46).

Good L2 learners demonstrate different patterns of strategy use from what poor learners employ. For instance, they tend to be attentive to form, monitor the speech of their own as well as others (Rubin, 1975, cited in Ellis, 1994, p. 547). They also attend to meaning, engage themselves actively in learning, and use more metacognitive strategies (see Ellis, 1994, pp. 546–550).

- Social distance

If a learner feels socially distant from the L2 community, he or she may not have a high motivation to integrate into that community and to participate in contact with the native speakers of the L2. This can lead to an inadequate amount of exposure and input, and hence hinder L2 acquisition (see Gass and Selinker, 2008, pp. 403–405). In consideration of the potential significance of such sociopsychological factors, Schumann (1978a, cited in Larsen-Freeman and Long, 1991, pp. 251–258) proposes the Acculturation Model to account for the process of SLA (see previous section).

To summarize, diverse factors related to the learning environment/setting and individual learners themselves can affect how well a second language is acquired. These variables do not function in isolation. Instead, they may be linked to each other. For instance, social distance may bear a close relationship to motivation, attitudes and affect. Aptitude may be interwoven with learning styles and learning strategies. Furthermore, learning styles may be influenced by personality, and the use of learning strategies is affected by various factors like age, motivation and the acquisition setting.

Besides those listed above, there are many other factors that more or less influence L2 acquisition too, e.g., memory, language disability, interest, birth order and prior experience with L1 (Larsen-Freeman and Long, 1991, pp. 203–206), as well as social class and ethnic identity (Ellis, 1994, pp. 204–210). But they are not as widely studied and their effects are not as significant or obvious as the aforementioned ones, thus they are not discussed here for the sake of brevity.

SLA in the Twenty-First Century

In the twenty-first century, SLA may develop toward an increasing diversity of research directions, growing attention to technology-related issues, and plurality of theoretical approaches. First, the scope of subject topics is broadening and research directions are expanding. In addition to the long-established areas such as L1 transfer, language universals and learner differences, more directions are emerging. For instance, a growing body of research in recent decades starts to investigate learner autonomy (e.g., in Dam, 2001), strategy training (e.g., Carrier, 2003) and task-based learning (e.g., in García Mayo, 2007).

Second, the development of CALL (Computer-Assisted Language Learning) triggers an array of technology-related topics worthy of investigation. Some questions waiting for exploration include the following: how to design effective CALL programs, how the mediation of technology affects the mental processes of learning, and in what way media literacy may influence the outcome of learning. For instance, Dodigovic (2005) discusses how to develop an intelligent CALL tool to assist L2 writing acquisition.

Thirdly, SLA theories are moving toward plurality. For one thing, established psycholinguistic, cognitive and sociocultural models will undergo new developments along with advances of related disciplines (e.g., cognitive science and psychology). For another, new sociocultural approaches may emerge within existent frameworks. For instance, there has been a growing interest in studying the negotiation and construction of learner identity (e.g., in Mantero, 2007) and the application of Vygotsky's sociocultural theory to SLA research.

With the increasing pace of globalization and the promotion of linguistic and cultural plurality in the modern age, it can be safely predicted that the population of second language learners and users will experience rapid growth in the new century. To account for the diversity of L2 sociocultural settings, a sound and comprehensive SLA theory in the future may well integrate the valid components from the various current approaches.

Conclusion

This article presents a general picture of SLA as an autonomous discipline of social science. It reviews the major theoretical approaches proposed in the field and examines a variety of factors that influence L2 acquisition. It also predicts some future directions of SLA research in the twenty-first century.

Abstract

World War II was, arguably, the most significant and influential event of the twentieth century. It was also a conflict with many faces – from the absolute 'barbarization' of the eastern front, to the 'war of a kind' in the Pacific, to something different in many other places. This article reviews the causes, course, and consequences of these multiple wars, paying special attention to the historiographical debates, which, in very many societies, have kept the war alive and meaningful in the generations since 1945. In that sense, it traces the history of a 'war that never ended.'

The Second World War: A Narrative

World War II was an event of massive significance. For at least 50 years after its end in 1945 it continued to condition societies and ideas throughout the world. Much of the politics of the second half of the twentieth century can be read as occurring in an 'after-war' context. The war exacted a death toll of at least 60 million, and probably tens of millions more than that (figures for China and the rest of Asia are mere guesses and the casualty figures on the extent of USSR's sacrifice has risen from 7 to 27 or more million as time has passed, circumstances varied, and the requirements of history altered). A majority of the casualties were civilians, a drastic change from World War I when some 90% of deaths were occasioned at the fronts. Moreover, the invention of the atom bomb during the war and its deployment by the USA at Hiroshima and Nagasaki (6 and 9 August 1945) suggested that, in any future nuclear conflict, civilians would compose 90% or more of the victims. When this apparent knowledge was added to the revelations of Nazi German barbarism on the eastern front, careless half-plans to eliminate 'some 30 million' of the peoples of the USSR and the Nazis' massacre of European Jewry, either in pit killings or when deliberately transported to such death camps as Auschwitz-Birkenau, Treblinka, Sobibor, Chelmno, Belzec, and Majdanek, another casualty of the war seemed to be optimism itself. Certainly at 'Auschwitz' and perhaps at Hiroshima, 'civilization,' the modernity of the Enlightenment, the belief in the perfectibility of humankind, had led not to hope and life but instead to degradation and death.

This more or less open fearfulness, with its automatic resultant linking of a pessimism of the intellect to any optimism of the will among postwar social reformers, may be the grandest generalization that can be made about the meaning of World War II. Big history, however, should not lose sight of microhistory. Actually World War II was fought on many fronts, at different times, for different reasons, and with different effects. In this sense, there was a multiplicity of World War IIs.

In September 1939, a war broke out between Nazi Germany and authoritarian Poland. The liberal democratic leadership of Britain and France intervened saying that they would defend Poland, although in practice they made do with 'phoney war' until the Nazi forces took the military initiative, first in Denmark and Norway, and then in the Low Countries and France in April–May 1940. In June 1940, Fascist Italy entered the war as had been envisaged in the 'Pact of Steel' signed with its Nazi ally in May 1939. War now spread to the Italian empire in North and East Africa and, from October 1940, to the Balkans. Italian forces botched what they had hoped would be a successful *blitzkrieg* against Greece and the effect over the next year was to bring most of the other Balkan states into the conflict, with drastic effect on the populations. Nazi-Fascist occupation was brutal and, moreover, often these fragile states dissolved into multiple civil wars, the most multifaceted and of one of the most lasting significance began in Yugoslavia from March to April 1941.

On 22 June 1941, the Nazi Germans invaded the Soviet Union, commencing what was, in some eyes, the 'real' World War II, and certainly the one that was inspired by the most direct ideological impulse, which unleashed the most horrendous brutality and which still remains, overtly or covertly the most disputed in its meaning. In the course of the campaign in the east it is estimated that the Germans sacked 1710 towns and 70 000 villages. During the epic siege of Leningrad from 1941 to 1944, a million of the city's inhabitants starved to death. In their invasion, the Germans were joined by an assortment of anti-communist allies and friends, including military forces from authoritarian Romania and Fascist Italy. Many Lithuanians, Latvians, and Estonians, and quite a few anti-Soviet elements within the USSR (Ukrainian nationalists, people from the Caucasus, and others) acted as auxiliaries of Nazi power. The Nazis were even embarrassed by a 'Russian' army under General A.A. Vlasov, willing to fight on their side against Stalin and his system. Volunteers also came from pro-Fascist circles in France, and from Spain and Portugal, states ruled by clerical and reactionary dictators who hated communists but were not fully reconciled to the radical racist thrust of much of the Nazi-Fascist rhetoric and some of the Nazi-Fascist policies.

On 7 December 1941, the war widened again when the Japanese air force attacked the American Pacific fleet at anchor at Pearl Harbor in Hawaii. In the following weeks, the Japanese army and navy thrust south and east, dislodging the British from Singapore by 15 January 1942. They went on to seize the Philippines and Dutch East Indies (later Indonesia) and were within striking distance of Australia before being checked at the Battle of the Coral Sea in June 1942. They simultaneously

continued the terrible campaign that they had been waging in China since 1937 (or rather since 1931, when they had attacked Manchukuo or Manchuria). In their special wars, the militarist Japanese leadership tried to throw off what they called the imperialist yoke of US capitalism and the older 'white' metropolitan empires. The purity of their antiimperial motives was damaged, however, by their own commitment to empire and by their merciless killing of Asians. Moreover, as in Europe, their invasions often touched off varieties of civil war provoked by the highly complex stratification of society in the region. At the forefront of such campaigns were often local nationalists who imagined communities subservient neither to European powers nor the Japanese.

On 11 December 1941, Germany and Italy, loyal to the terms of the anti-Comintern pact, had also declared war on the USA, somewhat ironically so, given that Japan, checked by military defeats in an unofficial war against the USSR at Khalkin Gol and Nomonhan in 1938–39, had now engaged with other enemies. The Italians would find out the implications in North Africa, the Germans after the Allied invasion of France on 'D-Day' (6 June 1944), as well as in Italy from 8 September 1943 (the Fascist dictator, Benito Mussolini, overthrown on July 25 in a curiously untotalitarian cabinet crisis, was thereafter restored as a German puppet in northern Italy; allied forces moved slowly up the peninsula from the south, liberating Rome on 4 June 1944 but only reaching Milan at the end of the war in late April 1945). Of the participants in the war, the USA, once fully mobilized, possessed the biggest and most productive economy, and was therefore of crucial importance in the eventual defeat of the anti-Comintern powers. The campaign that the Americans fought with the most intense passion, and with an evident racism of their own, was the war against Japan. In another sense, the USA had a relatively soft war, not disputed on its own territory and not requiring the sort of physical or spiritual sacrifice obligatory from most other combatants. The USA's special World War II was not a visceral one, except, perhaps, in its later imagination.

If the war was fought in many different ways, it is equally true that the variety of conflicts did not all end at the same time and in the same way. The Nazi armies surrendered on 8 May 1945, the Japanese on August 15. But matters were more complicated than that. France's special World War II would commemorate 'victory' from the date of the liberation of Paris on 25 August 1944 (and General Charles De Gaulle would have the effrontery to proclaim that Paris and France had liberated themselves). In most of Nazi-/Fascist-occupied Europe and in parts of Asia, partisan movements had never altogether accepted defeat. Communists were invariably prominent in such resistance, even if quite a few still envisaged themselves as fighting as much for the Soviet revolution as for the liberty of their own nation-state. Every successive 'liberation,' in Europe most frequently coming after the military victory of the Red Army, and in the Pacific that of the USA, had its own special character. Yugoslavia and China were two especially complicated places where the resistance was very strong but where it was contested, not only by the Nazi-Fascists and the Japanese but also by local anticommunist and nationalist or particularist forces. The effects and memory of their wars were by definition to be very different from such societies as in the USA, Australia, and the UK, which did not endure foreign occupation, though the last, with its severe experience of bombing, was itself different from the other two.

In sum, World War II was not just an enormously influential event but also an extraordinarily complicated one. Its complexity has in turn stimulated many passionate and long-lasting debates about its historical meaning.

The Causes of War

For many years it was customary to argue that World War II as compared with World War I had a simple cause. This was 'Hitler's war.' Mainstream analysis continues to ascribe to the Nazi dictator great responsibility for the invasion of Poland and for the spreading of the war thereafter, and especially for the launching of Operation Barbarossa against the USSR. To be sure, from the 1960s, the course of historiography, especially as exemplified in the rise of social history, itself eventually destined to be ousted by 'cultural history' during the rise of neoliberalism to its current hegemony, for a time did not favor a 'Great Man' view of the past and tended to urge that even dictators had limits to their free will. The English historian A.J.P. Taylor (1964) argued in a book entitled *The Origins of the Second World War* that the several crises which led up to September 1939 and what he sardonically called the 'War for Danzig' needed to be understood in a variety of contexts, including the peace settlements at the end of World War I, the course of German political and social history, the institutionalization of the Russian revolution, with its victorious but feared and paranoid communist and then Stalinist regime, and the lights and shadows of democratic liberalism in Western Europe.

Taylor wrote with a flaunted stylistic brilliance and practiced a brittle historical cleverness. He was frequently misunderstood and often gloried in the misunderstanding. His book thus produced an enormous and long-lasting controversy, still the greatest of many prompted by attempts to define the meaning of World War II. At the same time, Taylor's idiosyncrasies ensured that his work could easily be dismissed by those mainstream historians who cheered the weight of their commitment to Rankean principles.

Nonetheless the issues raised by Taylor did not go away. In West Germany, the so-called Fischer controversy, sparked by the Hamburg liberal historian Fritz Fischer's Griff nach der Weltmacht, a massively documented study of German aims during World War I and also published in 1961, raged through the decade and is still an object of historiographical debate. Although Fischer, then and thereafter, wrote almost exclusively about World War I and about imperial Germany, he was read as commenting on World War II and, indeed, on Germany's divided fate in its aftermath. Four issues were prominent. Was imperial Germany an aggressive power in a way that bore comparison with the Nazi regime during the 1930s? Was the motive of the German leadership as much domestic as foreign – did they seek foreign adventure and even world war in order to divert the pressure building for social democracy? Was the appalling conflict from 1939 to 1945 caused by the 'German problem,' which began as early as 1848 and continued after 1945? And was the real story of a European civil war lasting from 1914 to 1945?

Fischer's work was more directly influential than Taylor's and the issue of the relationship between *Innenpolitik* and *Aussenpolitik* fitted neatly into the preoccupations of new social historians who, by the 1970s, were scornfully dismissing the work of 'old fashioned diplomatic historians.' For all that, specialist works on the causation of World War II continued to privilege the power of Hitler and acknowledge the ideological thrust of Nazism. The English independent Marxist, Tim Mason, may have tried to pursue a Fischerian line in asking how much the diplomatic crises of 1938–39 were prompted by the contradictions of Nazi economic and social policy, but his essays remained at the periphery of most analysis. Rather such firmly Rankean historians as Gerhard Weinberg and Donald Watt assembled evidence which, in their eyes, confirmed that the war was caused by Hitler. The most authoritative English language biographer of the *Führer*, Ian Kershaw, despite his background in social history, has not disagreed. Hitler may have been erratic as an executive. Nazi totalitarian state and society, contrary to its propaganda about militant efficiency and a people cheerfully bound into a *Volksgemeinschaft*, may in practice have often been ramshackle. But the dictator, Kershaw argued, did possess power. Indeed, so all-embracing was his will that Germans strove to 'work toward' their *Führer*, to accept his ideas and implement his policies before he had fully formulated them. For a generation in the wake of the Fischer controversy, scholarship on Nazism separated into 'intentionalists' (advocates of Great Man history) and 'functionalists' (those who preferred to emphasize the role of structures and contexts and who were especially alert to the 'institutional darwinism' of the Nazi regime). By the late 1990s and after the fall of the USSR and the cementing of neoliberal hegemony, Kershaw, often a historian of the golden mean, found a way to resolve and end that conflict. It still holds.

The only major variants on this reaffirmation that Hitler had provoked the war came from certain conservative viewpoints. Some anticommunist historians focused on the Ribbentrop–Molotov pact (23 August 1939), placing responsibility for the war on 'Stalin' and the Russian revolution in what seemed to others a highly tendentious effort to blame the victim. More common was the view expressed most succinctly by Zionist historian Lucy Dawidowicz that the whole conflict was in essence a 'war against the Jews.' Hitler (or, in the variant made notorious by Daniel Goldhagen, the Germans) wanted to kill Jews; that was the purpose of the Nazi regime; that was the aim of its wars.

In other ex-combatant societies, further examples of local focus are evident. In England, fans of appeasement still existed, the most prominent being John Charmley. For him, the problem with the war lay simply in Britain's engagement in it. As far as the British Empire was concerned, Nazism did not need to be fought and the USSR should never have been an ally. Worst was the fact that the USA had dominated the postwar world. Charmley has never quite said so, but implication of his work is that the 'real' World War II for Britain, and the one it most dramatically lost, was implicitly fought against its American 'cousins.'

The Asian-Pacific conflict has similarly been subject to historical revision. In the 1960s Gabriel Kolko and other American 'new leftists' applied a Marxian model to their nation's foreign policy, critical of the gap between its idealistic and liberal theory and its realist and capitalist practice. They were in their turn subjected to withering fire from more patriotic and traditional historians. Nonetheless a consensus grew that, at least in regard to the onset of the American–Japanese war, US policy makers carried some responsibility. By the 1980s, liberal historian John Dower was even urging that the two rivals had been 'enemies of a kind,' neither of them guiltless of racism and brutality.

In Japan, by contrast, an officially sponsored silence long hung over everything to do with the war. The Ministry of Education was particularly anxious that schoolchildren not be exposed to worrying facts about such terrible events as the massacre in Nanking in 1937, the practice of germ warfare, the exploitation of 'comfort women,' and the other examples of Japanese murder, rape, and pillage in Asia and the Pacific. Nonetheless, a stubborn undercurrent of opinion exemplified in the work of historian Ienaga Saburō continued to contest the Ministry line and, by now, the Japanese leadership has gone further than ever before in admitting some of the misdeeds of its militarist predecessors. Fully critical history may still not be especially appreciated in Tokyo. But, Japan is not the only society to behave that way in a world where neoliberalism has achieved unparalleled hegemony backed by what American democratic historian Peter Novick has called 'bumper sticker' lessons from the past.

The Course of the War

In the preceding sections, it has not always been possible to keep fully separate discussions about the coming of World War II from what happened after hostilities commenced. In any case, military history in the pure sense, just like diplomatic history, after 1945 soon lost ground professionally. To most eyes, the military history of the war can swiftly enough be told. Of the anti-Comintern states, Germany and Japan but not Italy, won rapid initial victories, exulting in their respective *blitzkriegs*. But their triumphs were always brittle. Germany and its allies may have been good at launching wars, but their ideologies made it difficult for them thereafter to contemplate any policy except the complete liquidation of the enemy. Indeed having won their present battles, they often aimed at still further wars. Historian Adam Tooze (2006) argued strongly that the Nazis never abandoned a dream, extending beyond Europe, of a final confrontation with the USA. Hitler and the Japanese imperial and military leadership thus made no attempts to offer compromise from a position of strength, and Mussolini's occasional flirtation with the idea always involved Nazi sacrifice in their wars, especially that in the east, rather than Italian loss.

Nor did the anti-Comintern states make the most of the huge territories, which they had conquered, and the immense material resources that they therefore controlled. Nazi Germany is something of a case study in this regard. In the West, where the war was always gentler, the Nazis found plenty of direct and indirect collaborators. They were, for example, able to harness a considerable proportion of the French economy to their cause. They also started to construct a new economic order that was not utterly unlike some of the developments, which would occur in Western Europe after

Nazi-Fascism had been defeated. With extraordinary contradiction for a state built on an utter commitment to racial purity, Nazi Germany, already before 1939, needed immigrants to staff its economy. Once the war began, this requirement became more pressing. One partial solution was to import workers by agreement with its ally Italy and by arrangement with the friendly Vichy regime in France. Not all such French 'guest-workers' came unwillingly and not all had especially bad wars. In Germany they joined other, more reluctant, immigrants from the east, who were often little more than slave laborers. Poles and Soviet prisoners of war constituted the majority of these; at first they were frequently worked to death. However, as the Nazi armies turned back and the war settled into one of attrition and retreat, as symbolized by the great defeat at Stalingrad (November 1942–January 1943), the Germans began to treat even laborers from the east in a way that allowed some minimum chance of their survival and which also permitted some tolerable productivity from their labor.

The exception was, of course, the Jews, who, from September to October 1941, became the objects of the 'Final Solution,' a devotion to murder confirmed by officials who attended the Wannsee conference in January 1942. In terms of fighting a war, the adoption of the policy of extermination was, of course, counterproductive in many senses, among which was the economic. In staffing and fueling the trains, which transported the Jews to the death camps, in the low productivity of these and the other camps, the Nazis wasted resources needed at the front. Saul Friedlander will write elsewhere in this volume about the debates about the meaning of the Holocaust. It is worth noting in this segment, however, that each combatant society has argued about its particular experience of being visited by the Nazi war machine and therefore of being exposed to collaboration with it. Two important examples occurred in France and the USSR.

The spring of 1940 brought disaster to the Third French Republic. Now was the time of what Marc Bloch, one of the founders of the great structuralist historical school of the Annales, a patriotic Frenchman and a Jew, called the 'strange defeat.' Military historians have demonstrated that France was not especially inferior in armament to the invading Germans. Rather, France lost for reasons to do with morale and the domestic divisions of French society. As a result, by June 1940 the French state and empire collapsed. During the next 4 years, the inheritance of the Third Republic was disputed between the Vichy regime headed by Marshal Philippe Pétain within the rump of French metropolitan territories; the 'Free French' under General Charles De Gaulle, resident in London, and there, however reluctantly and churlishly, dependent on Allied goodwill and finance; and a partisan movement which gradually became more active in the occupied zones. This last was typically divided between communists and other forces, some of whom disliked communists as much as they hated the invaders. The years of Axis occupation were thus also the time of the 'Franco-French civil war,' with killings and purge trials extending well beyond liberation.

The meaning of war, occupation, and liberation in France was long disputed after 1945. It took a film maker, Marcel Ophuls in Le Chagrin et la pitié (1971), and an American historian, Robert Paxton, to break a generation of silence about the troubling implications of this period of national history, although Socialist President François Mitterrand (1981–95), with his own equivocal experience of Vichy, was scarcely an unalloyed advocate of openness during his term in office. Historian Henry Rousso has brilliantly examined the 'Vichy syndrome' and done much to expose some of the obfuscations favored by many different leadership groups in post-1945 French politics. Perhaps his work does not go far enough, however. With its fall, and then with decolonization after 1945, France had lost its political empire, promising to become just another European state. However, this loss was curiously compensated by the rise and affirmation of French culture. In almost every area of the humanities, such French intellectuals as De Beauvoir, Braudel, Barthes, Foucault, Lévi-Strauss, Lyotard, Baudrillard, and Nora, charted the way to post-modernity. They did so sometimes invoking the pro-Nazi philosopher Martin Heidegger and almost always without much reckoning of the collapse of the French nation-state in 1940 and often with its denial. The intellectuals of France were given to forgetting their nation's fall, the better to affirm their own rights to cultural imperium.

If France provides a case study of the transmutation of defeat into victory, the USSR offers the reverse example of a victor whose peoples would eventually learn that 'actually' they had lost. The nature of the Soviet war effort is still in need of research. Sheila Fitzpatrick, the key social historian of her generation, depicted a population by 1939 brutalized and depressed by the tyranny, incompetence, and contradictions of Stalinism, if also retaining agency of their own despite the dictatorship. Her work does not really explain, however, how that same populace fought so stubbornly 'for the motherland, for Stalin.' No doubt the absurd murderousness of Nazi policies gave them little alternative. No doubt the aid that eventually flowed from the USA was of great significance. But something does remain unexplained about how 'Stalin's Russia' won its 'Great Patriotic War.'

The Consequences of the War

By now very clear, however, are the consequences of the war for the USSR. In the short term the war made the Soviet state the second superpower, the global rival to the USA, and gave Stalin, until his death in 1953, an almost deified status. It also ensured, in the West, the rise of the theory of totalitarianism, which married communism and Nazi-Fascism as the common enemies of mankind. Initially a fruitful intellectual underpinning of the Cold War, this view of Europe's history from 1914 to 1945 and beyond has never been fully abandoned by its partisans, as has been demonstrated most graphically in recent times by Timothy Snyder's powerful but controversial book, Bloodlands. More generally, as the postwar decades passed, it became clear that the USSR and its expanded sphere of influence in Eastern Europe were not recovering from the war with the speed being dramatically exemplified in Western Europe and Japan. Indeed, the history of the USSR, at least until Gorbachev's accession to the party secretaryship in 1985 and, arguably, until the fall of the Berlin Wall and the

collapse of communism (1989–91), should best be read as that of a generation who had fought and won its wars (including the terrible domestic campaigns for collectivization as well as the purges of the 1930s). Leaders and people were unwilling or unable to move beyond that visceral experience. After 1945, the USSR became the archetypal place 'where old soldiers did not die nor even fade away.' Brezhnev, Chernenko, and their many imitators further down the power structure were frozen into a past that had an ever-diminishing connection with a world facing a new technological and economic revolution. So powerful was the war myth that it transferred cheerfully to Putin's Russia (and, in different form, to the various Soviet successor states), with communism obscured, nationalism enhanced (and with Stalin by no means renounced).

Other ex-combatant societies were more open to change than the USSR but a certain sort of remembering and a certain sort of forgetting can readily enough be located in them, too. Memory proved most threatening in Yugoslavia. There the victorious partisans under Josip Broz Tito seemed for a time to have won a worthwhile victory. The special history of their campaigns against the Nazi-Fascist occupiers of their country allowed them claims to independence from the USSR, which they duly exercised after 1948. At the same time the barbarity, during the war, of the collaborationist Croat-Fascist regime under Ante Pavelić, whose savagery embarrassed even the Germans, seemed to suggest that the region was indeed best administered by a unitary state. The fall of communism, however, also brought down a communist Yugoslavia in which such Serb leaders as Slobodan Milošević, unable to believe in official ideals, increasingly recalled the nationalism of wartime Cetniks rather than the internationalist Marxism once espoused by the partisans. This memory of war and murder justified new battles and new murders, even if with the somewhat ironical result that, in the Balkan wars of the 1990s, the (Serb) winners of the last conflict had become losers and the (Slovene, Croat, Bosnian Moslem, and Kosovar) losers had become winners.

In Italy, the country with the largest communist party in the West and a polity, which had a 'border idiosyncrasy,' bearing some comparison with Yugoslavia's role in the Eastern Bloc, the inheritance of war and fascism similarly possessed peculiar features. Postwar Italy began by renouncing fascism, empire, and war, in 1946 abandoning the monarchy that had tolerated the imposition of Mussolini's dictatorship and, in 1947, adopting a constitution which made considerable claim that the new Republic would be based on labor. In practice, however, Italy took its place in the Cold War West. Its purging of ex-Fascists was soon abandoned and both the power elites and the legislative base of the new regime exhibited much continuity with their Fascist predecessors. Nonetheless, from the 1960s, an ideology of antifascism was accorded more prominence in a liberalizing society. From 1978 to 1985, Sandro Pertini, an independent socialist who had spent many years in a Fascist jail and been personally involved in the decision to execute Mussolini, became Italy's president. Widely popular, he seemed an embodiment of the national rejection of the Fascist past.

Once again, however, the process of memory was taking a turn and a different useable past was beginning to emerge. Left terrorists in the 1970s had called themselves the new Resistance and declared that they were fighting a Fascist-style state – the governing Christian Democrats were thought to be merely a mask behind which lurked the Fascist beast. The murder of Aldo Moro in 1978 drove Italians decisively away from this sort of rhetoric and, from then on, Italians sought instead a 'pacification' with the past where ex-Fascists had as much right to be heard as ex-partisans. Among historians, 'anti-anti-Fascists,' led by Renzo De Felice, the biographer of Mussolini, provided evidence and moral justification for this cause. Media magnate and conservative politician Silvio Berlusconi joined those who agreed that an anti-Fascist World War II had lost its ethical charge, stating (wrongly) that 'Mussolini never killed anyone.'

Among the Western European ex-combatant states perhaps the UK was the place where the official myth of the war survived with least challenge, despite the huge casualty total in parts of the empire during the war, for example in the Bengal famine of 1943, for which at a minimum British incompetence must share some blame. A vast span of postwar British society and behavior was influenced by Britain's war. The Welfare State, as codified by the postwar Labor government under Clement Attlee, was explained and justified as a reward for the effort of the British people in the 'people's war.' Wartime conservative Prime Minister, Winston Churchill, despite his many evident limitations, remains a national icon. A royal wedding in 2011 had to be accompanied by a flyover from World War II planes. From the alleged acuteness of their secret service activities to the alleged idealism of their rejection of Nazism, the British have constantly sought to preserve the lion's share of the positives of World War II for themselves, almost as if it is their national version of a sacred holocaust. The suspicion toward the euro and much of the European Union and the many other examples of continuing British insularity often find historical justification in the view that the British fought alone against the Nazi-Fascists from 1940 to 1941, and express the associated annoyed perplexity that somehow their wartime sacrifice has entailed a slower passage to prosperity compared with that of their continental neighbors (and especially Germany).

Memory after memory, history after history, World War IIs, in their appalling plenitude, still eddy around. In 1999, for example, another historian wrote a major book about the meaning of an aspect of the war, and about the construction of that meaning. It is a work still of major importance. In it, Peter Novick daringly wondered whether the privileging of the Nazi killing of the Jews in contemporary Jewish and even gentile American discourse is altogether a positive. Being a historical victim at one time in the past, he argued cogently, can obscure as well as explain. His caution was timely. It is probably good that World War IIs are with us still; it will be better if the interpretation of so many drastic events can still occasion democratic debate, courteous, passionate, and humble debate, and if we can therefore avoid possessing a final solution to its many problems.

Abstract

Secrecy is deliberate concealment of information. Anthropologists are primarily interested in public, or institutionalized, secrecy: those persistent practices of hiding information within kinship, religious, political, or economic groups including state and corporate secrecy. Areas of research include concealment of ritual knowledge and the social functions of secret societies. Uses of more personal, or private, secrets have also attracted attention as these relate to cultural constructions of personhood and to the dynamics of interpersonal relationships. Some theorists have argued that society itself rests on a necessary interaction of surface and secret cultural systems. The study of secrets has posed obvious methodological and ethical problems for ethnographers.

Secrecy and Culture

A simple definition of secrecy as the deliberate concealment of information has served cross-cultural comparison (e.g., Tefft, 1980; Bok, 1982). Under this definition, people in cultures everywhere have secrets. Since a secret may turn out to be 'empty' – no hidden information in fact exists – some anthropologists have suggested that attention be refocused on the practice or the 'doing' of secrets rather than on a secret's informational content. Anthropologists have been primarily interested in what could be called public, or institutionalized, secrecy: those persistent practices of hiding information within kinship, religious, political, or economic groups. Areas of research have included concealments of ritual knowledge and the social functions of secret societies. More personal, or private, secrets have also attracted attention insofar as these relate to cultural constructions of personhood, identity construction, and the dynamics of interpersonal relationships. The study of secrets and institutionalized secrecy has posed obvious methodological and ethical problems for ethnographers.

Some have argued that secrecy is a fundamental aspect of all cultural systems. If culture is more or less shared knowledge, then the less shared, less public information creates and sustains people's cultural commitments and stokes their faith and emotional attachment to what they take to be important hidden truth. Truth, as locally and collectively accepted, gains power, significance, and attraction insofar as it remains partially hidden and opaque. Cultural worlds are often mysterious and partly obscured to those of us who inhabit them. Georg Simmel (1950 [1908]), who was among the first to remark the sociological significance of secrecy, suggested that secrets are a device of cultural 'adornment' – a jewel or bauble that seduces public attention. If the observable surface of everyday existence did indeed comprise all that there is, life would be more shallow and less interesting and, bored and unattached, one might disinvest in participating in society.

Secrecy, as a practice, is more significant than whatever information itself might be concealed. Furthermore, many analysts of secrecy systems have concluded that many secrets are not actually secret. Women know men's ritual tricks: those spirit voices overheard during religious ceremony are mere bamboo flutes or bullroarers. Children pretend not to know that their parents are the real Santa Claus. Kin from one lineage are familiar with the supposedly secret names, story archives, and genealogies of their neighbors. In oral societies, the leakiness of secret knowledge, in fact, helps maintain its viability within a community. If a secret holder dies, others are around to reveal lost knowledge if need be.

Suspicion of some truer reality, which lies hidden under the surface of life and explaining that life, is widespread (Ferme, 2001:4). What one sees is not all there is. In this argument, the canny and uncanny attractions of culture itself depend on a punctuated relationship between concealment and revelation. Michael Taussig, drawing on Elias Canetti and Michel Foucault, has argued that periodic revelation – the 'unmasking' of secrets – functions to burnish and empower society as mysterious and sacred: "For are not shared secrets the basis of our social institutions, the workplace, the market, the family, and the state?" (Taussig, 1999:2). Revelation, rather than draining cultural energy by unmasking concealed information, in fact, instead may 'animate the thing defaced and the mystery revealed may become more mysterious, indicating the curious magic upon which Enlightenment, in its elimination of magic, depends' (1999:3–4). Human culture is always partly secretive – recognized but not discussed. Such 'public' secrecy is 'that which is generally known, but cannot be articulated' (Taussig, 1999:5). It is this public willingness to accept and protect communal secrets, as in the story of the Emperor's new clothes, that maintains ruling cultural systems as well as claims to power and relations of inequality.

More specifically, ethnographers have focused on ceremonial masking, wrapping, and clothing practices that symbolize, enact, and demonstrate the distinction between manifest and secret truths. Spectators may or may not know the identity of the person obscured by a mask, but either way masking depersonalizes ritual actors who may thus become avatars of spirits and gods (De Jong, 2007:128). Ordinarily hidden reality rises to the surface insofar as the mask opens a door between seen and unseen. Wrapping objects in cloth or paper, similarly, creates a distinction between outside and inside, thus reflecting a fundamental opposition between surface and secret knowledge. Tattooing and clothing the human body similarly mark the boundary between interiors and exteriors. Gell, for example, suggests that Polynesian tattooing functioned as 'the exteriorization of the interior which is simultaneously the interiorization of the exterior'

(1993:39). Masking, wrapping, clothing, and tattooing, all call attention to the existence and interdependent relations between surfaces and interiors of both the person and society at large.

In addition to public cultural secrets, postponements of revelation also lubricate everyday social relationships. In these relationships, people tack between useful, ambiguous ignorance of each other's positions and desires so that the details of relational inequalities or disagreements need not be admitted or totted up and occasions when all is revealed (Piot, 1993). Secrecy here sets 'in motion a process—of interpretation, ambiguity, and the quest for hierarchy' and keeps this process in play (1993:362). Revelation, on the other hand, creates new relational and informational equilibria and starts the game anew.

Reading secrecy as an integral and fundamental aspect of culture itself parallels developments in queer theoretical analyses of literature, notably Eve Sedgwick's *Epistemology of the Closet* (1991), which locate unarticulated public secrets about sexuality hidden beneath the surface of the Western literary canon. Secrecy, likewise, is the dark shadow of culture itself, intertwined through all human affairs. Most anthropological theories of secrecy, however, are not so grand. They instead have focused on more particular practices and institutions of secrecy including secret organizations and societies and hidden aspects of personality.

The Paradox of Secrecy

The revelation of secrets is as important as the keeping of them. Ethnographers have called this the 'paradox' of secrecy (Bellman, 1984). For a secret to persist within a social order, it must eventually be told to someone who may in turn keep the secret until it passes along again. Information kept absolutely secret, and never revealed, eventually drops out of cultural orders. The social consequence of public secrets rests on the fact that people know of their existence even though content may remain hidden. Secrets with social consequence thus must be at least partly transparent and also periodically transacted and revealed.

Systems of secrecy often rely on inequalities in rights to reveal knowledge rather than on an effective concealment of information – rights that the Kpelle summarize in the term 'you cannot talk it' (Bellman, 1984). Folk copyrights of this sort regulate who may speak about what (Lindstrom, 1990). Even though many may know the content of concealed information, these unacknowledged others may not legitimately repeat and reveal this knowledge in public without the copyright to do so. Family groups in Vanuatu, for example, own songs, myths, genealogies, and medical recipes that others may not publicly reveal without that family's permission. In private contexts, however, public secrets are often surreptitiously discussed. Knowledge is thus regulated not only by restricted transmission – by secrecy – but also by copyrights that limit who speaks publicly about this. Folk systems of copyright transform secrets into public secrets. Those supposed not to know must pretend not to know, and those supposed to know pretend to think that only they, in fact, do know.

Public Secrecy

Public awareness of the existence of secrets can afford prestige and power to those who know what others do not. Many accounts of secrecy revisit Georg Simmel's ground-breaking analysis of secrecy and secret societies (1950 [1908]), including his observation that secrets are a form of 'inner property.' Simmel's commoditization of hidden knowledge opened the door to a political economy of secrecy. If secrets are property, then they are produced, exchanged, and consumed. Secrets are public because they have exchange value within a knowledge marketplace, and because such exchange has political consequence. Systems of political hierarchy may be grounded in an unequal distribution of secrets. Those who know may dominate those who do not know so long as the ignorant grant that hidden knowledge has value.

Anthropologists have used a political economy of secrecy to account for various forms of inequality. James Mooney, in 1887, revealed the 'sacred formulas' of Cherokee shaman and healers with which they built both professional pride and practice. Twenty years later, Franz Boas published details about northwest coast American secret societies, as did Edward Evans-Pritchard in Africa who infiltrated Azande secret magical associations (González, 2012). Much subsequent ethnographic attention has focused on West African secret societies as political institutions that maintain inequalities among elders and youth and men and women. Piot discriminates four predominantly functionalist anthropological approaches to African secrecy: the structural-functionalist, which concludes that secrecy maintains political unities and initiation societies; the Marxist, which argues that secrecy serves to empower elders over youth; the Freudian, which reads secrecy partly as a projection of infantile sexual anxiety; and the semiotic, which investigates the function of secrets within communicative systems (1993:354). All four approaches presume clear connections between secrets and power, although secrecy and secret organizations have sometimes maintained ruling political institutions while at other times have undermined these.

Secrecy and Power

In the latter years of the twentieth century, anthropological attention returned notably to issues of power and inequality. Neutral definitions of culture as more or less shared knowledge gave way to new concerns with the contradictions, gaps, variation, and disparity in that knowledge – with secrets, in fact. Secret knowledge and secret societies might not only have useful social functions, but also maintain ruling political and economic regimes. The distribution of access to public secrets typically parallels that of other rights and powers. Adults hide information from children, often until the latter have been ritually initiated into adulthood. Men refuse to share ritual knowledge with women. Family and lineage groups own various sorts of genealogical, medical, or historical knowledge, sharing these only among kin. Guilds and professions jealously guard business secrets and establish apprenticeships and other credentialing barriers to their proprietary technologies and other economic knowledge.

Conversely, secrecy can be a device to resist power. Or, in places where everyone has secrets – where secrecy is democratized – enduring political inequalities may be more difficult to establish insofar as 'the entire social order remains contingent, and the possibility of power, which is partly rooted in claims of privileged access to certainty, is greatly diminished' (Petersen, 1993:334). Secrecy protects ruling authority and those who resist this alike. Where hierarchy exists, the dominated conceal much of what they know from authority. Women preserve secrets they keep from men. Slaves commune in secret languages. Children construct hidden worlds that evade adult awareness. Secrecy here is a 'weapon of the weak,' which functions to resist and deflect supervision from above. It protects the lowly and the oppressed who must keep their heads down, be these wives, slaves, children, peasants, employees, and so forth. Secrecy can also protect adherents of heterodox religions, preserving their idiosyncratic beliefs and practices from public deprecation, as once was the case, for example, with middle-class English witches joined together in Wicca covens (Luhrmann, 1989).

Cants and other sorts of restricted linguistic codes also serve to restrict information flow. These include the professional jargons and argots spoken, for example, by doctors, lawyers, and thieves, and also a variety of youthful linguistic styles that elders may fail to grasp. Some traditional Bolivian healers speak Kallawaya, a secret trade language that combines Quechua grammatical forms and an esoteric vocabulary perhaps drawn from the now extinct Pukina language. Such cants preserve trade secrets and also obscure and conceal the everyday dealings of those who use them from the uninitiated. Arcane sacerdotal languages such as Latin and Sanskrit similarly create boundaries between insiders and outsiders, and may also usefully represent the mysteriously sacred voice of supernatural gods and spirits. In Melanesia, for example, ancestral spirit communiqués are often linguistically opaque to many insofar as only the adept can understand the secret language of spirits (Lindstrom, 1990:121).

Secret Societies

Anthropologists have pursued Simmel's original concern with secret societies, documenting a variety of secret groups, cults, associations, lodges, and clubs in cultures around the world the members of which are pledged to maintain secrets, ritual, and otherwise. The common comparative ethnographic category 'secret society' is catholic enough to encompass Melanesian men's houses and grade societies, Australian totemic cults, Native American medicine lodges, West African male and female associations, Western men's social clubs, and more (Webster, 1908).

Liberal theories of democratic process and of the capitalist marketplace have been suspicious of secrecy as they are of cabals and monopolies. Similarly, classic psychological models of personality and family dynamics have deprecated secrets and promoted personal revelation and storytelling as a form of healing. One should reveal hidden personal truth in order to 'shed light on the dark folds, to open the doors to the closets of secrecy, to engage the power of story as a way to penetrate – and perhaps lift ourselves out of – the darkness of despair' (Poulos, 2009:25). Just as persons and families cleansed of dark secrets are presumed to be healthier, so does democracy requires an informed citizenry. The capitalist marketplace, too, is supposed to depend on the free flow of economic information among buyers and sellers. From this perspective, secrecy generally goes against the public good. Secret societies have frequently aroused public suspicion about their operations and goals, suspicion that has frequently led to legal and sometimes violent suppression of suspect groups. Those left in the dark have often been outraged by and mistrustful of secret organizations: "For about a century and a half large numbers of intelligent Europeans believed that much of what was happening in the world around them only happened because secret societies planned it so" (Roberts, 1972:1–2).

Although often mistaken, conspiracists on the lookout for hidden powers and forces have at least occasionally been correct in their suspicions. Some secret organizations have indeed aimed to topple established authority, just as witches, sorcerers, and shaman may actually, and secretly, attempt to kill others (Whitehead and Wright, 2004). In recent years, some West African secret societies, which once protected village political interests, have turned against the state in support of one or another rebel movement in Liberia, Sierra Leone, and elsewhere (De Jong, 2007). Earlier, European colonial authority likewise mistrusted secret society operations in West Africa as it did Melanesian 'cargo cults' in the southwest Pacific.

There are more ethnographic accounts of establishment rather than revolutionary secret societies. Structural-functionalist analysis suggests that traditional secret societies in Africa and elsewhere commonly serve important social functions, including the education of children, preservation of political authority, punishment of lawbreakers, stimulation of the economy, and the like (Little, 1949). Such 'social' secret societies address important community needs, unlike 'antisocial' secret societies whose goals are criminal or revolutionary (Wedgewood, 1930). For example, the power of Kpelle elders over youth in Liberia is grounded in their management of the secrets of the Poro society (Murphy, 1980). Elders across Sierra Leone and Liberia initiate young men into Poro and young women into a parallel female Sande secret society. Acknowledging the authority of their elders, initiates pay to join these societies and they eventually will themselves become the knowledgeable elite. In addition to accessing revealed knowledge, society initiates also learn adult practices of discretion and dissimulation (Bellman, 1984:51). In postcolonial times, these West African secret societies have also come to modulate local community relations with state authority and with global economic and other cultural forces that increasingly reach into once isolated villages (De Jong, 2007).

Beyond West Africa, anthropologists have argued that elder male keepers of secrets similarly acquired authority over women and uninitiated youth in various societies of Melanesia (Barth, 1975), Native America (particularly Southwestern Pueblo cultures), and Australia (Keen, 1994). Melanesian cult secrecy, for example, typically not only aimed to avoid colonial scrutiny but also functioned as a means 'of understanding the cultural differences between Europeans and Melanesians' insofar as cultists presumed European power also to rely on hidden knowledge (Lattas, 1998:73). Cult ideology suspected that all powerful knowledge – local

and foreign – need be secret. Male appropriation of religious ritual, access to the supernatural, technology, medicine, sacred texts, history, and other valued information cemented their authority over the ignorant. Furthermore, women, children, and others in subordinate political positions sometimes can be forced to reveal what they know, or otherwise denied rights to secrecy. Rights to keep secrets are as consequential as the right to reveal information.

Personal Secrecy

Ethnographic attention to notions and practices of personal secrecy overlaps with legal theories of the person and policy initiatives to protect rights of privacy that the US Supreme Court delineated beginning in the 1920s. Concepts of private secrets reflect cultural assumptions about personhood. Persons, too, comprise a public face or surface that overlies hidden truths. To have secrets, a person must encompass some sort of inner self or heart where private information and opinion are stored along with intentions and capacity to conceal this information. One might imagine a culture that entertains notions of persons with no inner selves that would thus obviate the possibility of private secrets. No such culture exists although Western conceptions of childhood often presume that psychologically immature children lack complete competence with secrecy – that personal aptitude to intentionally conceal information only emerges as part of the child developmental process (Bok, 1982). Literature and film, e.g., *The Invention of Lying*, have sometimes imagined humans without inner selves and private secrets, but if such persons exist today they are taken to be psychologically immature or insane.

Western historians have suggested that there have been different regimes of secrecy in the past, related to shifts in constructions of personhood. Simmel (1950 [1908]) connected the evolution of secrecy to that of individualization and urbane modernity (his argument recalls similar evolutionary accounts of personal privacy). In preurban societies, lack of individualism and everyday intimacies of interpersonal contact within small human communities made secrecy difficult. Simmel supposed that secrets increased with developing opportunities for personal reserve and discretion. More recent historians, stimulated by the work of Michel Foucault (1978), have argued instead that modernity shrinks opportunities for personal secrecy – that bureaucratic power structures increasingly have come to rely upon the monitoring of individuals, either through self-revelation or by institutional and technological devices that extract personal information. According to Foucault, the origins of such extraction trace back to the Christian practice of confession. People are obliged to reveal their secrets to ecclesiastical, juridical, and other authorities, and revealing secrets to authority confirms ones subjugation within a social order.

After the Enlightenment, sincerity and authenticity emerged as predominant modern virtues, displacing previous appreciation of personal ability to mask and to dissimulate (Snyder, 2009). Being authentic to one's own inner truths and maintaining sincerely within one's personal relationships, both can degrade onetime boundaries between public face and private secrets. Some fear such trends have now gone too far, energized and encouraged by contemporary technology. The revelation of private selves on Facebook to vastly greater numbers of spectators, corporate, and otherwise, for example, may threaten what remains of personal privacy. The modern individual, however, still possesses inner capacities to conceal information although these capacities struggle nowadays with contradictory urges and duties to reveal those secrets.

Stimulated by the work of Erving Goffman (1959) and others, students of interpersonal relationships have remarked the significance of secrets, masks, and 'face' within the everyday micropolitics of self-presentation. Such studies have noted social uses of revelation. People strengthen their relationships, creating communities of trust, by revealing secret information. This may be a secret about themselves, or a secret about another that they pass along, often in return for the promise 'not to tell.' Such secrets are a kind of gossip (Bok, 1982), the exchange of which remarks and maintains sentiments of friendship. American girls, for example, establish and strengthen friendships by sharing secrets. They also end such friendships by spilling these secrets to third parties. Personal secrets are a social currency that people invest in their relationships. Public secrets maintain political value insofar as their transmission is restricted, whereas the value of personal secrets flows from their easy everyday revelation.

Alongside preservation of regimes of power, secrecy also contributes to perceptions of individual identity. Self-understanding may transform after a person has acquired secret information. Boys, for example, come to redefine themselves as men after progressing through an initiation ritual during which they learn adult secrets (Herdt, 2003). One's acquisition of once hidden knowledge marks achievement of adulthood. Those who join secret societies may gradually access more and more esoteric knowledge, and this growing purchase on hidden reality marks their increasing status and authority within a community.

Anthropological analyzes of the personal dynamics of public secrets prefigured work on other similar institutions, including the homosexual 'closet,' a term that has now come to characterize all sorts of personal secrets that are either unknown or ignored by others (Sedgwick, 1990). *Yan Daudu*, for example, men who have sex with men in the Hausa Islamic areas of northern Nigeria and who also embrace aspects of feminine style, manage to operate within their communities insofar as others overlook the quasisecret queer spaces they create (Gaudio, 2009). This is also true of the men, typically married, with whom they enjoy sexual relationships. Such 'do not ask, do not tell' practices and policies serve to maintain multipart persons. The closet, like more general practices of clothing, masking, and wrapping, map out a layered personhood, which comprises a public face floating atop an inner, private self.

State and Corporate Secrecy

Institutional secrecy has accelerated with developing digital technologies that not only store and make available but also conceal information. States, corporations, and other contemporary institutions are often reticent to release information that does not serve their interests. At the same time,

they employ increasingly powerful data mining techniques to access and aggregate personal information. Public debate about limitations and rights to online privacy are currently underway. Although anthropologists have been encouraged to 'study up,' typical ethnographic methods including participant observation and interviewing are difficult to deploy when investigating governmental or business organizations that actively deflect outside attention. Some ethnography of such institutions and their secrecy practices has been undertaken, although this ground has been better covered by investigative journalists. Ethnographers have managed to study notoriously secret organizations including American intelligence agencies, government nuclear and other research laboratories, and the US military's Human Terrain System that was initiated during the Iraq and Afghanistan wars (González, 2012). Ethnographers have also focused on corporations and their internal organization but typically have acquired access only to the less secretive corners of these enterprises such as human resource management, product marketing campaigns, or whatever corporate culture they are willing to acknowledge.

The Study of Secrecy

Anthropology's interest in cross-cultural description as a whole has been taken to be the desire to learn and reveal other people's secrets (Taussig, 1999; De Jong, 2007:189). Anthropological authority rests on the ability to penetrate cultural screens. Methodologically, ethnographers face obvious problems of access to concealed information, but the study of secrecy raises even larger ethical puzzles. Ethnographers who infiltrate cultural systems can sometimes be accused of stealing secrets or being troublesome snitches. Codes of ethics generally require ethnographers to ensure that their research does not harm the safety, dignity, or privacy of the people they study. The 2009 Code of Ethics of the American Anthropological Association, for instance, requires that researchers must not disguise their objectives, their sources of support, or the potential impacts of their projects and, in general, should appropriately use and disseminate their research results. The code, however, recognizes that every case is different and that an ethical duty not to harm the dignity, safety, or privacy of informants may require maintaining confidentiality and their anonymity, as well as sometimes not publishing or otherwise disclosing research findings. Some ethnographers who investigate secrecy have described the structure and function of secrecy systems while avoiding publishing the details of secret knowledge content. Others have promised not to make their publications or photographs available to members of a community (women, often, or the uninitiated) who should not have access to secret information. A few have refrained from publishing at all and restrict access to their field notes for varying lengths of time.

Ethical issues are thorniest where the secrets that anthropologists probe help sustain unjust social orders. Duty to protect the interests of one's informants becomes more difficult when these are in powerful positions or organizations, and spilling the secrets of whom might in fact encourage greater social justice. Some have also noted that current ethical practices of 'informed consent,' wherein subjects must first understand and then consent to be studied, presume the existence of rational actors operating in public arenas in which information is shared and facts are transparent (Mitchell, 1993:24). Others argue that such presumptions of normative transparency and impartial contractual obligations between researchers and their subjects are not supported by more sophisticated theories of cultural secrecy (as above) that take the social world 'to be shot through with misinformation, evasion, lies, and fronts and every level, and research in kind – secret, covert, concealed, and disguised – is necessary and appropriate' (1993:30). Ethnographic attention to the secrecy practices of state and corporate bureaucracies certainly has required some dissimulation insofar as these organizations generally command the ability to evade and repel academic scrutiny. Despite the best efforts of these organizations, some information leaches out via the Internet. Sites such as wikileaks.org collect and collate formerly secret information. Researchers have also deployed Freedom of Information Laws, where these exist, to penetrate state secrets (González, 2012). Like state and corporate bureaucracies, ethnographers too can data mine at least some of the concealed information now digitally circulating around the world.

Secular Religions

Arthur L Greil, Alfred University, Alfred, NY, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The term 'secular religions' can be used to describe certain apparently secular enterprises that appear to share common features with enterprises usually thought of as 'religious.' Pursuing the analogy between such enterprises and religion raises serious theoretical questions concerning the proper definition of religion, the process of secularization, and the nature of religion in contemporary societies. Within contemporary sociology and anthropology, there exist several different research traditions that focus on the boundary between the religious and the secular, including the 'civil religion' approach, the 'implicit religion' tradition, the 'religious forms' approach, and the study of 'quasireligion.'

The term 'secular religions' can be used to describe certain apparently secular enterprises that appear to share common features with enterprises usually thought of as 'religious.' 'Secular religion' is one of several terms – including 'civil religion,' 'invisible religion,' 'parareligion,' and 'quasireligion' – which draw attention to religious and religious-like beliefs and activities that do not fit easily into the Western folk conception of religion as a distinct institutional structure focused on a transcendent being or beings.

Examples of 'Secular Religions'

At first blush, the very notion of 'secular religion' would appear to be an oxymoron. In both popular and sociological usage, the term 'religion' is typically associated with the realm of the 'sacred' and contrasted with that of the 'secular.' However, a number of scholars have pointed out striking similarities between ostensibly religious and ostensibly secular undertakings. Secular ideologies, it is argued, may, like religions, unite followers into a community of shared beliefs. They may provide adherents with a sense of meaning and ultimate purpose. They may inspire in believers a sense of transcendence usually associated with religion. Attempts to find parallels between the sacred and the secular have been especially common in studies of the political realm and in studies of therapeutic organizations and activities.

Political 'Religions'

Zuo (1991) has described the veneration of Chairman Mao during the Chinese Cultural Revolution as a political religion replete with sacred beings (Mao himself), sacred texts (the Little Red Book), and rituals (political denunciations). Gentile (1996) and others have described Fascism as secular religion. The term 'political religion' has also been employed to describe attempts made in developing societies to rally support for the concept of the nation. Crippin (1988) has gone so far as to argue that nationalism is the religion par excellence in modern society and that it is displacing more traditional forms of religion.

O'Toole (1977) has used the term 'sect' to describe certain political groups operating in Canada, including the Socialist Labor Party, followers of De Leon who wait for a communist millennium, which they regard as imminent. Social movements such as environmentalism (Brinkerhoff and Jacob, 1991), the animal rights movement, and the health food movement have been described as quasireligions insofar as they provide adherents with a coherent worldview and sense of purpose at the same time that they command a great deal of loyalty.

Therapeutic 'Religions'

Many scholars have drawn attention to the ritual aspects of Western medical practice. Others have pointed out that psychiatrists have much in common with shamans and other religious healers. A number of researchers have pointed out the similarities that exist between self-help groups and religious organizations (Galanter, 1989; Rudy and Greil, 1988). One family within the self-help movement that is perhaps more obviously 'religious' in character than most of the others includes Alcoholics Anonymous (AA) and other twelve-step or codependency groups. A few among many of the religious characteristics of AA are a conception of the sacred, ceremonies and rituals, creedal statements, experiences of transcendence, and the presence of an AA philosophy of life.

Other Examples

Other examples of attempts to point out analogies between apparently secular enterprises and religious ones abound in the social scientific literature. Within the realm of sport, attention has been paid to ritual elements and experiences of transcendence to be found in cricket, baseball, football, and the Olympic Games. It has now become commonplace among students of corporate culture to regard such activities as meetings, presentations, and retirement dinners as rituals. Ashforth and Vaidyanath (2002) have analyzed work organizations in general as secular religions. Some writers have drawn attention to the sectarian characteristics of certain types of businesses, such as home-party sales organizations and direct sales organizations. Voluntary organizations that have been interpreted as quasireligions include the Boy Scouts, groups of hobbyists and collectors, and 'fan clubs.' Jindra (1994) has described the phenomenon of Star Trek 'fandom' as religious in that it provides participants with a common worldview and inspires

 http://dx.doi.org/10.1016/B978-0-08-097086-8.32129-8

high levels of commitment. Several writers have attempted to characterize atheism itself as a religious enterprise, characterizing Ethical Culture and other humanist groups as analogous to religions. Still others have viewed faith in science as the dominant religious perspective of the contemporary era.

'Secular Religions' and the Problem of Defining Religion

It may be argued that an interest in secular religion is a natural outgrowth of the functionalist perspective in classical sociology, which tended to view religion as serving a necessary function for the maintenance of society by uniting members of a society into a common moral universe. If, as many early sociologists thought, supernaturalistic conceptions of the universe were destined to recede in the face of industrialization and the increasing influence of science, the question arose as to what phenomena might serve as the 'social cement' of future societies. Comte's call for a 'religion of humanity' qualifies as an early sociological mention of the notion of a 'secular religion.' Durkheim's expectation that a 'cult of the individual' might play a similar role in the maintenance of society as that traditionally played by religions represents another early effort to provide intellectual justification for the idea that apparently secular ideologies may have religious characteristics.

As appealing and intuitive as the idea that secular enterprises may share important features with religions might be, the notion of a 'secular religion' must confront theoretical problems concerning the appropriate sociological definition of 'religion' and of 'the sacred.' Functional definitions of religion emphasize that the essential element in religion is the provision of an encompassing system of meaning or the ability to connect people to the ultimate conditions of their existence. Substantive definitions of religion argue that what distinguishes religion from other types of human activity is its reference to the sacred, the supernatural, or the superempirical.

The advantage of functional definitions is a breadth and inclusiveness that allows one to look at beliefs and practices not commonly referred to as religious but that may nonetheless resemble religious phenomena in important ways. One major disadvantage is that they may have the effect of so broadening the concept of religion that it becomes meaningless. While substantive definitions avoid this problem, they may result in allowing traditional Western conceptions of the nature of religion to determine what is to be included in the 'religious' category. Viewed from the perspective of the debate over the definition of religion, the theoretical problem with the concept of 'secular religion' is that it seems to rely simultaneously on both a broad functional approach to religion and a narrower substantive approach. The idea that environmentalism or nationalism could be properly called a religion relies on a functional definition, while the idea that such religions are 'secular' rather than 'sacred' necessarily depends on a substantive definition.

One might argue that both functional and substantive definitions of religion share the weakness that they privilege social scientists' conceptions of religion over folk conceptions of religion, that is to say the ways that people use the term 'religion' in everyday life. Some social scientists would therefore argue that the search for a scientifically valid definition of religion is futile and that the best that can be done is to define religion ethnographically, treating it as a 'category of discourse' with meanings that are changeable over time. The position that scholars take with regard to these definitional issues will necessarily influence the way in which they approach the study of 'secular religions.' This is perhaps one reason why there is at present no consensus within the social sciences with regard to the most appropriate method for studying phenomena residing on the border between the sacred and the secular.

Approaches to the Study of 'Secular Religions'

Within contemporary sociology and anthropology, there exist several different research traditions that focus on the boundary between the religious and the nonreligious.

The Notion of Civil Religion

While Rousseau coined the term 'civil religion,' its development as a social scientific concept is attributed to Bellah (1967). Working within the functionalist tradition, which sees religion as integrative for society, Bellah argued for the existence of an American civil religion, an 'institutionalized collection of sacred beliefs about the American nation,' which binds Americans together in spite of denominational pluralism. A key tenet of American civil religion is the conception of the United States as a nation with a divinely ordained mission. Although the civil religion concept was developed in the American context, it has been applied to the analysis of many states including Canada, Israel, and Malaysia.

The Implicit Religion Tradition

Although the term 'implicit religion' was coined and popularized by Bailey (1983), the concept owes much to the work of Luckmann (1967). Working with a broad functional definition of religion as the transcending of biological nature and the formation of a self, Luckmann argues that religion is a human universal. Luckmann maintains that traditional religions have become irrelevant in the modern world but that religion, rather than disappearing, has become personalized, privatized, and 'invisible.' Following Luckmann's lead, Bailey's implicit religion approach looks for the experience of the sacred within events of everyday life ordinarily dismissed as profane. Thus, in a study of interaction in an English public house, Bailey interprets the ethos of 'being a man,' mastering alcohol, and respecting the selves of others as implicitly religious.

The Study of 'Religious' Forms

There also exist a relatively large number of studies of general social 'forms' that are deemed to be relevant in both sacred and secular contexts. General discussions of 'secular ritual,' for example, fall into this category. Goffman's (1967) work on the functional significance of such rituals of everyday life as 'saving face' and showing 'deference' is particularly well known. Collins (1981) treats 'interaction ritual chains' as a key element

in his attempt to lay a microsociological foundation for macrosociology. Once conversations, social greetings, and athletic contests are allowed to count as ritual, ritual becomes virtually coterminous with social life. For this reason, some scholars reject 'ritual' as a meaningless category, while others argue that the ubiquity of ritual simply means that ritualizing is a fundamental human activity.

Many sociological studies of the commitment process either explicitly or implicitly present the commitment process as operating in much the same way in both sacred and secular contexts (Kanter, 1972). Some writers have developed models of the identity change process that highlight the similarity between religious conversion and other forms of identity change (Galanter, 1989). Studies that employ the term 'sect' in the analysis of apparently secular organizations have already been discussed.

The 'Quasireligion' Approach

The quasireligion approach popularized by Greil (1993) and his colleagues relies on an ethnographic approach to the term 'religion,' regarding it not as an objective category susceptible to social scientific definition but as a claim negotiated in the course of social interaction. Greil distinguishes between parareligions and quasireligions. Parareligions, which are ostensibly nonreligious entities that nonetheless deal with matters of ultimate concern, resemble the enterprises referred to in this article as 'secular religions.' The term 'quasireligion,' on the other hand, refers to groups, like AA or certain occult groups, which deal with matters of transcendence or ultimate concern, but which do not see themselves or present themselves unambiguously as religious. The concern here is not to determine whether a particular group is or is not a quasireligion but to examine the process by which particular groups attempt to claim or repudiate the religious label and by which other groups and individuals respond to these claims.

The Theoretical Significance of Secular Religions

Pursuing the analogy between ostensibly secular enterprises and 'religion' as it is usually conceived raises important questions concerning the proper definition of religion, the process of secularization, and the nature of religion in contemporary societies. The study of secular religions puts into bold relief the problematic nature of social scientific attempts to define religion. How one defines religion has important consequences for how one thinks about secular religions and for whether or not one regards the concept as useful. Attention to religious border phenomena presses one to consider the value of an ethnographic approach to definition that conceptualizes religion as a category of discourse whose precise meaning and implications are continually being negotiated in the course of social interaction. The study of secular religions also directs attention to difficulties in specifying and evaluating the secularization thesis, which claims that the influence of religion is declining in contemporary societies. It should be clear that one's approach to the question of secularization (including whether one even conceives of secularization as a theoretical possibility) depends on one's definition of religion and on one's treatment of religious border phenomena.

Several of the approaches to secular religion discussed here imply that traditional Western conceptions of religion as an institutionalized set of beliefs and practices focusing on a transcendent deity is beginning to lose its hold over many people. Likewise, many people seem to be tending to give expression to their experiences of transcendence in institutional contexts that have not typically been thought of as religious. If this is, in fact, the case, the line between religion and nonreligion may be expected to become even more blurred and the study of religious border phenomena even more central to the social scientific enterprise.

Abstract

In its precise historical sense, 'secularization' refers to the transfer of persons, things, meanings, etc., from ecclesiastical or religious to civil or lay use. In its broadest sense, often postulated as a universal developmental process, secularization refers to the progressive decline of religious beliefs, practices, and institutions.

In its precise historical sense, 'secularization' refers to the transfer of persons, things, meanings, etc., from ecclesiastical or religious to civil or lay use. In its broadest sense, often postulated as a universal developmental process, secularization refers to the progressive decline of religious beliefs, practices, and institutions.

The Term 'Secularization'

Etymologically, the term secularization derives from the medieval Latin word *saeculum*, with its dual temporal-spatial connotation of secular *age* and secular *world*. Such a semantic connotation points to the fact that social reality in medieval Christendom was structured through a system of classification which divided 'this world' into two heterogeneous realms or spheres, 'the religious' and 'the secular.' This was a particular, and historically rather unique, variant of the kind of universal dualist system of classification of social reality into sacred and profane realms, postulated by Émile Durkheim.

In fact, Western European Christendom was structured through a double dualist system of classification. There was, on the one hand, the dualism between 'this world' (the City of Man) and 'the other world' (the City of God). There was, on the other hand, the dualism within 'this world' between a 'religious' and a 'secular' sphere. Both dualisms were mediated, moreover, by the sacramental nature of the church, situated in the middle, simultaneously belonging to both worlds and, therefore, able to mediate sacramentally between the two.

The differentiation between the cloistered *regular* clergy and the *secular* clergy living in the world was one of the many manifestations of this dualism. The term secularization was first used in canon law to refer to the process whereby a religious monk left the cloister to return to the world and thus become a secular priest. In reference to an actual historical process, however, the term secularization was first used to signify the lay expropriation of monasteries, landholdings, and the mortmain wealth of the church after the Protestant Reformation. Thereafter, secularization has come to designate any transfer from religious or ecclesiastical to civil or lay use.

Secularization as a Historical Process

Secularization refers to the historical process whereby the dualist system within 'this world' and the sacramental structures of mediation between this world and the other world progressively break down until the medieval system of classification disappears. Max Weber's expressive image of the breaking of the monastery walls remains perhaps the best graphic expression of this radical spatial restructuration initiated by the Protestant Reformation. This process, which Weber conceptualized as a general reorientation of religion from an other-worldly to an inner-worldly direction, is literally a process of secularization. Religious 'callings' are redirected to the *saeculum*. Salvation and religious perfection are no longer to be found in withdrawal from the world but in the midst of worldly secular activities. In fact, the symbolic wall separating the religious and the secular realms breaks down. The separation between 'this world' and 'the other world,' for the time being at least, remains. But, from now on, there will be only one single 'this world,' the secular one, within which religion will have to find its own place. To study what new systems of classification and differentiation emerge within this one secular world and what new place religion will have within it is precisely the analytical task of the theory of secularization.

Obviously, such a concept of secularization refers to a particular historical process of transformation of Western European Christian societies and might not be directly applicable to other non-Christian societies with very different modes of structuration of the sacred and profane realms. It could hardly be applicable, for instance, to such 'religions' as Confucianism or Taoism, insofar as they are not characterized by high tension with 'the world' and have no ecclesiastical organization. In a sense those religions which have always been 'worldly' and 'lay' do not need to undergo a process of secularization.

In itself such a spatial-structural concept of secularization describes only changes in the location of Christian religion from medieval to modern societies. It tells very little, however, about the extent and character of the religious beliefs, practices, and experiences of individuals and groups living in such societies. Yet the theory of secularization adopted by the modern social sciences incorporated the beliefs in progress and the critiques of religion of the Enlightenment and of Positivism and assumed that the historical process of secularization entailed the progressive decline of religion in the modern world. Thus, the theory of secularization became embedded in a philosophy of history that saw history as the progressive evolution of humanity

from superstition to reason, from belief to unbelief, from religion to science.

The Secularization Paradigm

Secularization might have been the only theory within the social sciences that was able to attain the status of a paradigm. In one form or another, with the possible exception of Alexis de Tocqueville, Vilfredo Pareto, and William James, the thesis of secularization was shared by all the founders. Paradoxically, the consensus was such that for over a century the theory of secularization remained not only uncontested but also untested. Even Durkheim's and Weber's work, while serving as the foundation for later theories of secularization, offer scant empirical analysis of modern processes of secularization, particularly of the way in which those processes affect the place, nature and role of religion in the modern world. Even after freeing themselves from some of the rationalist and positivist prejudices about religion, they still share the major intellectual assumptions of the age about the future of religion.

For Durkheim, the old gods were growing old or already dead and the dysfunctional historical religions would not be able to compete with the new functional gods and secular moralities which modern societies were bound to generate. For Weber, the process of intellectual rationalization, carried to its culmination by modern science, had ended in the complete disenchantment of the world, while the functional differentiation of the secular spheres had displaced the old integrative monotheism, replacing it with the modern polytheism of values and their unceasing and irreconcilable struggle. The old churches remain only as a refuge for those 'who cannot bear the fate of the times like a man' and are willing to make the inevitable 'intellectual sacrifice.'

Only in the 1960s one finds the first attempts to develop more systematic and empirically grounded formulations of the theory of secularization in the works of Acquaviva (1961), Berger (1967), Luckmann (1963), and Wilson (1966). It was then, at the very moment when theologians were celebrating the death of God and the secular city, that the first flaws in the theory became noticeable and the first systematic critiques were raised by Martin (1969) and Greeley (1972) in what constituted the first secularization debate. For the first time it became possible to separate the theory of secularization from its ideological origins in the Enlightenment critique of religion and to distinguish the theory of secularization, as a theory of the modern autonomous differentiation of the secular and the religious spheres, from the thesis that the end result of the process of modern differentiation would be the progressive erosion, decline and eventual disappearance of religion. Greeley (1972) already pointed out that the secularization of society, which he conceded, by no means implied the end of church religiosity, the emergence of 'secular man,' or the social irrelevance of religion in modern secular societies. Yet after three decades the secularization debate remains unabated. Defenders of the theory tend to point to the secularization of society and to the decline of church religiosity in Europe as substantiating evidence, while critics tend to emphasize the persistent religiosity in the United States and widespread signs of religious revival as damaging counterevidence that justify discarding the whole theory as a 'myth.'

The Three Subtheses of the Theory of Secularization

Although it is often viewed as a single unified theory, the paradigm of secularization is actually made up of three different and disparate propositions: secularization as differentiation of the secular spheres from religious institutions and norms, secularization as general decline of religious beliefs and practices, and secularization as privatization or marginalization of religion to a privatized sphere. Strictly speaking, the core and central thesis of the theory of secularization is the conceptualization of the historical process of societal modernization as a process of functional differentiation and emancipation of the secular spheres – primarily the state, the economy, and science – from religion and the concomitant specialized and functional differentiation of religion within its own newly found religious sphere. The other sub-theses, the decline and privatization of religion, were added as allegedly necessary structural consequences of the process of secularization. Maintaining this analytical distinction should allow the examination and testing of the validity of each of the three propositions independently of each other and thus refocus the often fruitless secularization debate into comparative historical analysis that could account for obviously different patterns of secularization.

The Differentiation and Secularization of Society

The medieval dichotomous classification of reality into religious and secular realms was to a large extent dictated by the church. In this sense, the official perspective from which medieval societies saw themselves was a religious one. Everything within the *saeculum* remained an undifferentiated whole as long as it was viewed from the outside, from the perspective of the religious. The fall of the religious walls put an end to this dichotomous way of thinking and opened up an entire new space for processes of internal differentiation of the various secular spheres. Now, for the first time, the various secular spheres – politics, economics, law, science, art, etc. – could come fully into their own, become differentiated from each other, and follow what Weber called their "internal and lawful autonomy." The religious sphere, in turn, became a less central and spatially diminished sphere within the new secular system, but also a more internally differentiated one, specializing in 'its own religious' function and losing many other 'non-religious' (clerical, educational, social welfare) functions (Luhmann, 1977). The loss in functions entailed as well a significant loss in hegemony and power.

It is unnecessary to enter into the controversial search for first causes setting the modern process of differentiation into motion. It suffices to stress the role which four related and parallel developments played in undermining the medieval religious system of classification: the Protestant Reformation; the formation of modern states; the growth of modern capitalism; and the early modern scientific revolution. Each of the four developments contributed its own dynamic to modern processes of secularization. The four of them together were certainly more than sufficient to carry the process through.

The Protestant Reformation by undermining the universalist claims of the Roman Catholic church helped to destroy the old organic system of Western Christendom and to liberate the secular spheres from religious control. Protestantism also served to legitimate the rise of bourgeois man and of the new entrepreneurial classes, the rise of the modern sovereign state against the universal Christian monarchy, and the triumph of the new science against Catholic scholasticism. Moreover, Protestantism may also be viewed as a form of internal secularization, as the vehicle through which Christian religious contents were to assume institutionalized secular forms in modern societies, thereby erasing the religious/secular divide.

If the universalist claims of the church as a salvation organization were undermined by the religious pluralism introduced by the Reformation, its monopolist compulsory character was undermined by the rise of a modern secular state which progressively was able to concentrate and monopolize the means of violence and coercion within its territory. In the early absolutist phase the alliance of throne and altar became even more accentuated. The churches attempted to reproduce the model of Christendom at the national level, but all the territorial national churches, Anglican, Lutheran, Catholic, and Orthodox, fell under the caesaro–papist control of the absolutist state. As the political costs of enforcing conformity became too high, the principle *cuius regio eius religio* turned into the principle of religious tolerance and state neutrality toward privatized religion, the liberal state's preferred form of religion. Eventually, new secular *raison d'état* principles led to the constitutional separation of church and state, even though some countries such as England and the Scandinavian Lutheran countries may have maintained formal establishment.

Capitalism, that revolutionizing force in history which according to Marx 'melts all that is solid into air and profanes all that is holy,' had already sprouted within the womb of the old Christian society in the medieval towns. No other sphere of the *saeculum* would prove more secular and more unsusceptible to religious and moral regulation than the capitalist market. Nowhere is the transvaluation of values which takes place from Medieval to Puritan Christianity as radical and as evident as in the change of attitude toward 'charity' – that most Christian of virtues – and toward poverty. Following Weber (1958), one could distinguish three phases and meanings of capitalist secularization: in the Puritan phase, 'asceticism was carried out of monastic cells into everyday life' and secular economic activities acquired the meaning and compulsion of a religious calling; in the utilitarian phase, as the religious roots dried out, the irrational compulsion turned into 'sober economic virtue' and 'utilitarian worldlines'; finally, once capitalism 'rests on mechanical foundations,' it no longer needs religious or moral support and begins to penetrate and colonize the religious sphere itself, subjecting it to the logic of commodification (Berger, 1967).

The conflict between the church and the new science, symbolized by the trial of Galileo, was not as much about the substantive truth or falsity of the new Copernican theory as it was about the validity of the claims of the new science to have discovered a new autonomous method of obtaining and verifying truth. The conflict was above all about science's claims to differentiated autonomy from religion. The Newtonian Enlightenment established a new synthesis between faith and reason, which in Anglo-Saxon countries was to last until the Darwinian crisis of the second half of the nineteenth-century. Across the Channel, however, the Enlightenment became patently radicalized and militantly anti-religious. Science was transformed into a scientific and scientistic worldview which claimed to have replaced religion the way a new scientific paradigm replaces an outmoded one.

As each of these carriers – Protestantism, the modern state, modern capitalism, and modern science – developed different dynamics in different places and at different times, the patterns and the outcomes of the historical process of secularization varied accordingly. Yet it is striking how few comparative historical studies of secularization there are which would take these four, or other, variables into account. David Martin's *A General Theory of Secularization* is perhaps the single prominent exception. Only when it comes to capitalism has it been nearly universally recognized that economic development affects the 'rates of secularization,' that is, the extent and relative distribution of religious beliefs and practices. This positive insight, however, turns into a blinder, when it is made into the sole variable accounting for different rates of secularization. As a result, those cases in which no positive correlation is found, as expected, between rates of secularization and rates of industrialization, urbanization, proletarianization, education, in short, with indicators of socio-economic development, are classified as 'exceptions' to the 'rule.'

The Decline of Religion Thesis

The assumption, often stated but mostly unstated, that religion in the modern world was declining and would likely continue to decline has been until recently a dominant postulate of the theory of secularization. It was based primarily on evidence from European societies showing that the closer people were involved in industrial production, the less religious they became, or at least, the less they took part in institutional church religiosity. The theory assumed that the European trends were universal and that non-European societies would evince similar rates of religious decline with increasing industrialization. It is this part of the theory which has proven patently wrong.

One should keep in mind the inherent difficulties in comparative studies of religion. Globally, the evidence is insufficient and very uneven. There is often no consensus as to what counts as religion and even when there is agreement on the object of study, there is likely to be disagreement on which of the dimensions of religiosity (membership affiliation, official vs. popular religion, beliefs, ritual and nonritual practices, experiences, doctrinal knowledge, and their behavioral and ethical effects) one should measure and how various dimensions should be ranked and compared.

Nevertheless, one can prudently state that since World War II, despite rapid increases in industrialization, urbanization, and education, most religious traditions in most parts of the world have either experienced some growth or maintained their vitality (Whaling, 1987). The main exceptions were: the rapid decline of primal religions mostly in exchange for more 'advanced' ones (mainly Islam and Christianity), the sudden and dramatic decline of religion in communist countries, a process which is now being reversed after the fall of

communism, and the continuous decline of religion throughout much of Western Europe (and, one could add, some of its colonial outposts such as Argentina, Uruguay, New Zealand, and Quebec).

What remains, therefore, as significant and overwhelming evidence is the progressive and apparently still continuing decline of religion in Western Europe. It is this evidence which has always served as the empirical basis for most theories of secularization. Were it not for the fact that religion shows no uniform sign of decline in Japan or the United States, two equally modern societies, one could still perhaps maintain the 'modernizing' developmentalist assumption that it is only a matter of time before the more 'backward' societies catch-up with the more 'modern' ones. But such an assumption is no longer tenable. Leaving aside the evidence from Japan, a case which should be crucial, however, for any attempt to develop a *general* theory of secularization, there is still the need to explain the obviously contrasting religious trends in Western Europe and the United States.

Until very recently, most of the comparative observations as well as attempts at explanation came from the European side. European visitors have always been struck by the vitality of American religion. The United States appeared simultaneously as the land of 'perfect disestablishment' and as 'the land of religiosity *par excellence*.' Yet, Europeans rarely felt compelled to put into question the thesis of the general decline of religion in view of the American counterevidence. Religious decline was so much taken for granted that what required an explanation was the American 'deviation' from the European 'norm.' The standard explanations have been either the expedient appeal to 'American exceptionalism' or the casuistic strategy to rule out the American evidence as irrelevant, because American religion was supposed to have become so 'secular' that it should no longer count as religion (Luckmann, 1963).

From a global–historical perspective, however, it is the dramatic decline of religion in Europe that truly demands an explanation. A plausible answer would require a search for independent variables, for those independent carriers of secularization present in Europe but absent in the United States. Looking at the four historical carriers mentioned above, neither Protestantism nor capitalism would appear as plausible candidates. The state and scientific culture, however, could serve as plausible independent variables, since church–state relations and the scientific worldviews carried by the Enlightenment were significantly different in Europe and America.

What the United States never had was an absolutist state and its ecclesiastical counterpart, a caesaro–papist state church. It was the caesaro–papist embrace of throne and altar under absolutism that perhaps more than anything else determined the decline of church religion in Europe. Consistently throughout Europe, nonestablished churches and sects in most countries have been able to withstand the secularizing trends better than the established church. It was the very attempt to preserve and prolong Christendom in every state and thus to resist modern functional differentiation that nearly destroyed the churches in Europe.

The Enlightenment and its critique of religion became themselves independent carriers of processes of secularization wherever the established churches became obstacles to the modern process of functional differentiation or resisted the emancipation of the cognitive–scientific, political–practical, or aesthetic–expressive secular spheres from religious and ecclesiastical tutelage. In such cases, the Enlightenment critique of religion was usually adopted by social movements and political parties, becoming in the process a self-fulfilling prophecy. By contrast, wherever religion itself accepted, perhaps even furthered, the functional differentiation of the secular spheres from the religious sphere, the radical Enlightenment and its critique of religion became superfluous. Simply put, the more religions resist the process of modern differentiation, that is, secularization in the first sense, the more they will tend in the long run to suffer religious decline, that is, secularization in the second sense.

The Privatization of Religion Thesis

As a corollary of the thesis of differentiation, religious disestablishment entails the privatization of religion. Religion becomes indeed 'a private affair.' Insofar as freedom of conscience, 'the first freedom' as well as the precondition of all modern freedoms, is related intrinsically to 'the right to privacy' – to the modern institutionalization of a private sphere free from governmental intrusion as well as free from ecclesiastical control – and inasmuch as the right to privacy serves as the very foundation of modern liberalism and of modern individualism, then indeed the privatization of religion is essential to modern societies.

There is, however, another more radical version of the thesis of privatization which often appears as a corollary of the decline of religion thesis. In modern secular societies, whatever residual religion remains becomes so subjective and privatized that it turns 'invisible,' that is, marginal and irrelevant from a societal point of view. Not only are traditional religious institutions becoming increasingly irrelevant but, Luckmann (1963) adds, modern religion itself is no longer to be found inside the churches. The modern quest for salvation and personal meaning has withdrawn to the private sphere of the self. Significant for the structure of modern secular societies is the fact that this quest for subjective meaning is a strictly personal affair. The primary 'public' institutions (state, economy) no longer need or are interested in maintaining a sacred cosmos or a public religious worldview.

The functionalist thesis of privatization turns problematic when instead of being a falsifiable empirical theory of dominant historical trends, it becomes a prescriptive normative theory of how religious institutions ought to behave in the modern world. Unlike secular differentiation, which remains a structural trend that serves to define the very structure of modernity, the privatization of religion is a historical option, a 'preferred option' to be sure, but an option nonetheless. Privatization is preferred internally as evinced by general pietistic trends, by processes of religious individuation, and by the reflexive nature of modern religion. Privatization is constrained externally by structural trends of differentiation which force religion into a circumscribed and differentiated religious sphere. Above all, privatization is mandated ideologically by liberal categories of thought which permeate modern political and constitutional theories.

The theory of secularization should be free from such a liberal ideological bias and admit that there may be

legitimate forms of 'public' religion in the modern world, which are not necessarily anti-modern fundamentalist reactions and which do not need to endanger either modern individual freedoms or modern differentiated structures. Many of the recent critiques and revisions of the paradigm of secularization derive from the fact that in the 1980s religions throughout the world thrust themselves unexpectedly into the public arena of moral and political contestation, demonstrating that religions in the modern secular world continue and will likely continue to have a public dimension.

Abstract

This article focuses on the historical evolution of the concept of 'secularization' in sociology and philosophy. It does not include a description of political systems and their approach to religion and secularity. The authors dwell on the classic secularization thesis and explain how this thesis was questioned in sociology and philosophy alike. The secularization debate nowadays counts many participants reflecting diverging normative positions. Despite this multitude of positions and nuances, the debate is likely to continue in the future along two particular strands: first, discussions on the use of concepts as secular/post-secular and the tenability of the religious/secular divide; second, discussions that will revolve around Western modernity/multiple modernities, or 'the West versus the rest.'

Definition, Etymology, and Classic Secularization Thesis

Secularization is a multilayered concept with at least four layers of meaning (cf Gorski and Altimordu, 2008, pp. 59–60). First, secularization etymologically derives from the Latin world *saeculum*, meaning 'century' in worldly time, as opposed to *eternitas*, eternal life where human, worldly concepts of time have no meaning or to *eschaton*, the end of times. In medieval canonical law, *saecularizatio* refers to a monk's exit from his monastery and his return to the world. The third layer dates from the period of reformation, when Protestant leaders seized church properties. As such, the concept of secularization first emerges as a French neologism in the sixteenth century, in a theological – literary essay by Pierre Crespet (1543–94) (Monod, 2002, p. 20). In 1690 the concept reappears in the posthumously published dictionary of Antoine Furetière (1619–88) with a slightly different meaning. There the entry refers to the transformation of ecclesiastic possessions, for example, the reconversion of monasteries to hospitals or universities, or to the selling of ecclesiastic goods for civil purposes. This material meaning of the process of secularization also prevails between 1648 and 1803, when church goods are rendered a worldly status as a result of the peace of Westphalia and the policy of Napoleon, respectively (Monod, 2002, p. 21). The thus far final layer of meaning emerges at the end of the nineteenth century: secularization as the political project of a secularist movement (Gorski and Altimordu, 2008, p. 61). Hence, secularization will always denote a transition from a religious to a more worldly level.

All these shades of meaning shine through in the so-called classic secularization thesis, that is, the idea that modernization would, with a sort of inner necessity, eventually lead to the disappearance of religion (De Vriese, 2010, p. 408; Gorski and Altimordu, 2008, p. 56). Adherents of the classic secularization thesis saw religion and secularization as strongly opposed to each other. Not only from a historical perspective – first there was religion, and then came secularization – but also from an ideological angle both were generally presented as antipodes. In that perspective, religion was deemed as irrational whereas secularization was considered as the product of rational progress.

Secularization Thesis under Pressure

Due to a number of historical events, the classic secularization thesis has become controversial during the last decades. The Iranian Revolution of 1979, the upsurge of the Moral Majority, the New Christian Right and Evangelicalism in the United States, the political upheaval due to fundamentalist radicalization in several countries: these and analogous developments all over the world have undermined the paradigmatic status of the secularization thesis and have given rise to a huge controversy within modern social sciences as to its objective basis (De Vriese, 2010, pp. 410–412, Habermas, 2008, p. 2)

This controversy has led to various positions among sociologists and philosophers alike. First, some scholars continue to defend the classic secularization thesis, albeit in a more moderate form. Secularity is definitive in some societies and secularization continues to progress in other societies, but the prediction that religion would entirely disappear does no longer make sense. However, the boosters of the secularization thesis remain convinced that modernity in all its ramifications has diminished the significance of religion. In this respect, the differentiation of societal functions and scientific disciplines (e.g., psychology, economy, and sociology) that formerly pertained to religion counts as one of many explanatory factors. More moderate adherents of the classic thesis argue for secularization as the best warrant for religion to flourish on a basis of freedom and equality in relation to nonreligious outlooks.

The number of adherents to the classic secularization thesis is gradually being outweighed by an increasing amount of scholars who explicitly reject its hegemony. They point to thriving religiosity on a global scale, or even see signs of desecularization within Western, allegedly, secular societies. Religion will continue to play an important role, both in the private and in the public sphere, and is entitled to do so.

Another angle from which to look at the secularization debate is that of transcendental and genealogical accounts of secularization, which have multiplied in recent years. These genealogical narratives focus on the hidden transcendental background – ideological, rhetorical, psychological, and epistemological – behind the adherence or opposition to the secularization thesis. A number of scholars (Marcel Gauchet, Jürgen Habermas, Charles Taylor, Robert Bellah, and José Casanova),

 http://dx.doi.org/10.1016/B978-0-08-097086-8.03113-5

precisely because they are aware that theories on secularization are shaped at a much deeper, often unconscious transcendental level, aim at a clarification of the concept. Although these scholars depart from a common historical and genealogical approach, their ways part when it comes to their evaluation of secularization. In this sense, the secularization debate cannot escape meta-historical normativity.

This brief introduction into the etymology of the concept of secularization and to the current debate of secularization is elaborated in the following four sections. We begin with a selective overview of the debates in sociology; we then turn to the field of philosophy; these overviews set the stage for a reflection upon the relation between the concepts of 'post-secular,' 'secularization,' and 'secularism.' Finally, we make a (much too small) digression on the non-Western view on the concept of secularization.

Sociology of Secularization: A Selective Overview

The origin of the sociological secularization theory is strongly related to *Max Weber*'s thoughts on the rise of capitalism and its protestant origins in *The Protestant Ethic and the 'Spirit' of Capitalism*. With the rise of modern capitalism, Weber claims, money becomes a goal in itself and is no longer subservient to 'higher goals,' let alone religious ones. Weber traces this evolution back to the spirit of Protestantism. Certain strands of Protestantism, such as Calvinism, developed a theory of predestination. Man's fate is regulated by divine providence. Every person's salvation depends solely on God's grace. This paradoxically made Calvinist believers strive for worldly success. The more wealth one could accumulate within earthly existence, the firmer the proof of election by God. Of course, the economic works by man were seen as homage, an act of gratitude to the benedictions of God. But by the same token, a lot of energy was invested in worldly affairs, which were eventually cut loose from their divine purposes.

Indirectly influenced by Weber, *Peter Berger* argued in the 1960s, most notably in *The Sacred Canopy*, for a theory of secularization that considered modernization and secularization as causally connected. In other words, the general thrust of his argument was that modernity inevitably undermined the social significance of religion. As to the causes and the results of the loss of function of religion, there was a divergence of opinion. Some argued that the future of religion was complete extinction (Wallace, 1966), some attributed more weight to social or religious changes, such as the industrial revolution or the protestant reformation (Berger, 1969) than to the growth of scientific knowledge, while others thought vice versa. However divergent in the detailed elaboration of their positions, during the late 1960s and early 1970s, most sociologists of religion embraced, one way or another, the secularization thesis in its basic form.

By the late 1970s or early 1980s, the majority of sociologists of religion came to agree that the original secularization thesis was untenable in its basic form. That change was primarily inspired not by any change in theological or philosophical positions, but by the massive weight of empirical evidence, the 'revenge of facts' (De Vriese, 2010). Most conspicuously, it was Berger himself, one of the founding fathers of the classic secularization theory, who in his 1999 edited volume *The Desecularization of the World*, renounced his earlier theory in unequivocal terms, by stating that the classic secularization theory is 'essentially mistaken' (Berger, 1999, p. 2). Other scholars proclaimed that God was back (Micklethwait and Wooldridge, 2009).

One of the most extreme voices in this debate among proponents and opponents of the secularization theory was that of *Rodney Stark*. Already in the mid-1980s he and his collaborators vehemently attacked the then dominant secularization theory as propounded by Wallace and Berger. Stark and his colleagues' point of departure was a rather idiosyncratic definition of secularization as a decline in individual belief and practice, based on what they called a supply-side or religious economies model. This model allowed them to argue that neither the United States nor even Western Europe was really secularized. In the case of the United States, this is clear enough: although indisputably modern (urbanized, industrialized, democratic, and so on), it is not secular in terms of demand and supply (high rate of church attendance and membership; even higher rate of belief in God and an afterlife). But in their view, Europe is not secular either. That the levels of church attendance and church membership are lower than in the United States, is not due to a decline in religious demand but rather to structural deficiencies in the religious supply, that is, the age-old state-regulated structures of Europe's religious market. Since Stark considers religious demand as a constant and since he defines secularization as a deficiency in religious supply, he concludes that the secularization doctrine may be carried to the graveyard of failed theories (Stark, 1999, pp. 269–270; cf Gorski and Altimordu, 2008, p. 57; De Vriese, 2010, p. 409).

Admittedly, Berger's recantation of his earlier theory and Stark's outspoken dismissal of secularization as such did remain controversial. In particular, Stark, Finke, and Iannaconne's alternative supply-side model and their end-of-secularization declaration were charged as being oversimplified and much too individualistic. Mainly in reaction to the supply-side model of sociology, divergent sociologists of religion have been highlighting the supra-individual aspects that are at play in relation between religion and secularization (the power of ecclesiastical elites and institutions, cultural and symbolic structures, and so on). They claim that the process of secularization is a highly complicated multileveled process, going far beyond the demand of and supply for individual actors. Among them, there are both opponents and defenders of the secularization theory.

The most prominent defender of what is coined as the neoorthodox secularization thesis is the British sociologist *Steve Bruce*. Why neoorthodox? On the one hand, Bruce recognizes the complexity of the secularization process: he is fully aware of its cross-national varieties and historical contingencies. On the other hand, he remains embedded in the rather ahistorical and teleological background of the classic secularization theory by positing the strong link between modernization and secularization (Gorski and Altimordu, 2008, p. 59; Bruce, 2011, pp. 27, 223). Another proponent of the neoorthodox strand is *Gregory S. Paul*, who has done some effort to statistically prove correlations between democracy, secularity, and affluence (Paul, 2005, 2010).

Due to increasingly divergent definitions of secularization, the Belgian sociologist *Karel Dobbelaere* undertook an attempt at clarification. He distinguished between three levels of analysis: the individualization and privatization of religious practice and belief (micro-level); the emergence of competitive religious markets (meso-level); and the functional differentiation of societal subsystems (macro-level) (Dobbelaere, 1999). Analogous to Dobbelaere, *José Casanova* distinguishes three different connotations of the term secularization so as to overcome the impasse in the secularization debate: (1) secularization as the *decline* of religious beliefs and practices; (2) secularization as the *privatization* of religion (see also Luckmann, 1967, 1996); and (3) secularization as the *differentiation* of the secular spheres (Casanova, 1994, 2006, p. 7; Gorski and Altimordu, 2008, pp. 56–58). While the 'decline' and 'privatization' sub-definitions have been heavily criticized in the last decades, the 'differentiation' thesis remains relatively uncontested in the social sciences (Casanova, 2006, p. 9). But even then, the question remains whether it is correct to subsume the different geographical and historical patterns of differentiation into a universal process of modernization.

Each endeavor to find an answer to that latter question presupposes a genuine awareness of its complexity. Not only does one have to take into account the influence of a new concept, that is, that of 'multiple modernities,' first developed by *Shmuel N. Eisenstadt* (cf infra), but also one must realize as well that the vicissitudes within the evolution of secularization are one way or another strongly linked with internal transformations of religion. Therefore, parallel to elaborating a multilayered concept of secularization we are in need of a new concept of religion, seen in the light of their mutual relations.

Grace Davie and *Danièle Hervieu-Léger* have been working on this topic, albeit from different angles. Davie characterizes the contemporary situation in Western Europe as 'believing without belonging.' The normative link between a religious identity, belief in dogmatic propositions, and regular church practice does no longer hold for a majority of 'believers.' Hervieu-Léger offers a different, even reverse characterization of the same European situation as 'belonging without believing.' But these, at face value contradictory characterizations, illustrate the emergence of a new concept of religion that was coined by Davie as 'vicarious religion.' This concept indicates that people do not always connect explicitly to a specific religious tradition, but approve as a tacit majority of the religious activities ('belonging') or religious beliefs of an active minority (Davie, 1994, 2000; Hervieu-Léger, 1999, 2004; Casanova, 2006, p. 14; Taylor, 2007, pp. 513–514, 521–522). It exemplifies the unmistakable fact, at least in Europe, that the religious and the secular mutually condition each other (Casanova, 2006, pp. 10–14)

Is a conclusion possible from this selective overview? Hardly. It may be clear that the classic secularization thesis, once hegemonic, now finds itself in an increasingly defensive position. But that does not mean that everyone is equally prepared to dispense with the theory altogether. The debunkers are accompanied by the believers and both of them are criticized by many revisionists who opt for a redefinition of the concepts of secularization and religion alike.

Viewed over a longer period from the nineteenth to the twenty-first centuries, this evolution in the sociology of religion parallels the evolution within the domain of philosophy of religion. In post-World War II philosophy, prominent philosophers, in search for a redefinition of the concept of secularization, also favor a three-tiered scheme. Mutual references between sociologists and philosophers abound. As a consequence, main protagonists such as Weber, Gauchet, Taylor, Casanova, and so many others in the debate on the concept of secularization are figuring prominently in general reviews of sociological and philosophical journals alike (De Vriese, 2010, pp. 409–410; Taylor, 2007; Gauchet, 1997; Gorski and Altimordu, 2008).

Philosophy of Secularization: A Selective Overview

Philosophical debates reflect a profound analogy with the sociological views on secularization. First, we have the classic secularization thesis that interprets modernity as a dynamic of ongoing progress, at the cost of 'irrational' religion. In this respect, *Auguste Comte*'s positivistic view of the relation paved way for contemporary views about the irrationality or superfluity of religion in the light of scientific progress. Although the so-called 'new atheists' Richard Dawkins (2006), Daniel Dennett (2006), Sam Harris (2004), and Christopher Hitchens (2007) are, in view of sociological data, well aware that religion will not easily disappear from the globe, they nonetheless express their hope that it would wither away – and that the light of reason would further conquer the world. What distinguishes the philosophical debates about secularization from the sociological debates – despite many intersections – is the more overtly normative tone.

Max Weber (1905) also took the rationalization of culture as a key element of modernity. But unlike Comte, he deems religion capable of self-rationalization. Monotheistic religious traditions vehemently criticize magical practices of the so-called 'natural' religions. Monotheistic thinking thus breeds the possibility of modern science, eventually leading to what Weber famously called the disenchantment or 'Entzauberung' of the world. However, Weber is not unequivocally happy about disenchantment. He blames scientific rationality and its instrumental logic for creating an 'iron cage' around human society, analogous to what *Charles Taylor* (2007) has called a disembedded society, consisting of 'buffered selves.' Weber's link between capitalism and protestant ethics can be regarded as well as an example of the internal capacity of religion for self-transformation, and a warning against simplifying theories which state that 'science has substituted religion' – or will eventually do so.

In line with Weber, and also with political philosopher *Carl Schmitt*, *Karl Löwith* questioned modernity and its self-acclaimed originality. In *Meaning in History* (1949), Löwith coined a new (philosophical) secularization paradigm, that of *modernity as an illegitimate transfer* of previously religious elements to a worldly level. The transfer is illegitimate, because one cannot untie secular concepts or practices from their religious framework, without perverting the original purpose of the religious concepts and practices. For example, the Christian concept of 'hope' was deeply intertwined with a transcendent, eschatological perspective on life after death. It was by no means directed toward an inner-worldly total solution for suffering. Redemption was solely possible in the afterlife. It was only with the Franciscan movement inaugurated by Joachim of Fiore (1135–1202) that the priority of

transcendent eschatology over inner-worldly affairs was questioned. Löwith considers modernity as the heir of this Franciscan movement. When modernity transforms Christian hope into the modern idea of progress, totalitarian ideologies see their chance to promote inner-worldly goals leading to ultimate salvation *in this life*. To underline their undeniable kinship with religious schemes, *Marcel Gauchet* has called these totalitarians views – communism, fascism – in line with *Eric Voegelin* 'secular religions.'

Hans Blumenberg opposed Löwith's paradigm of secularization. He defends modernity's original claims in his classic book *The Legitimacy of the Modern Age* (1966, transl. 1983). Secularization did not come about by an illegitimate transition from Christian hope to the modern idea of progress. Medieval eschatology was not primarily based on the hope for salvation, but on the fear of condemnation. This fear was theologically deepened by the nominalist account of a voluntarist and almighty God, who could at any time alter the 'ratio' of his own creation arbitrarily and totally whimsically. Hence, man could no longer be considered as the image of a God whose almighty will and thinking infinitely transcend the human condition, nor could nature be seen as the reflection of a divine plan of creation. As a result, man was left on his own, squeezed between an almighty but capricious *deus absconditus* on the one hand, and a whimsical and irrational nature on the other. According to Blumenberg, this predicament gave rise to the modern idea of self-assertion ('Selbstbehauptung'): man had to enhance his unenviable position by becoming master and commander of nature by his own rationality, and not by understanding God's rationality. Modern science developed in this context as a perfectly legitimate endeavor.

In more recent decades, philosophers like Taylor and Gauchet, and (philosophically oriented) sociologists like *Robert Bellah* have clearly widened the scope of the Löwith – Blumenberg debate. This debate revolved around the relation between Christianity and modernity in very specific historical figures: that of Joachism in the case of Löwith, the figure of nominalism in Blumenberg's account. While these two perspectives on secularization remain true for their part, Taylor, Gauchet, and Bellah esteem that they only tell a relatively small part of the story. Ground for this suspicion lies in *Karl Jaspers' Vom Ursprung und Ziel der Geschichte* (1949; Eng. transl. 1953), where Jaspers questioned Christianity's centrality in the rise of modernity by pointing to the importance of what he coined as the era of 'axial religion,' in the period of about 800–200 BC. Bellah, Gauchet, and Taylor continue to recognize the pivotal importance of Christianity, but place that importance in a larger story about the evolution of religion.

In *The Disenchantment of the World*, Gauchet considers secularization on a political level as the irreversible transition from heteronomy to autonomy. Gauchet states that this political autonomy could only arise from deeper ontological evolutions. He claims somewhat paradoxically that the 'reign of the invisible' or 'transcendence' first needs to be articulated more deeply, in order to eventually drift away from the 'visible' or 'immanent' world. The axial age and the Judeo-Christian tradition precisely constitute historical stages that articulate ontological dualism, and thus make it possible to ultimately separate the transcendent from the immanent. Gauchet follows Weber in his description of this evolution as 'disenchantment.' Gauchet sees Christianity as the penultimate stage of disenchantment (prior to the Enlightenment, with the rise of modern science, historical consciousness, and the French Revolution), depicting Christianity as 'the religion for the departure from religion' – *la religion de la sortie de la religion*. He calls the process of disenchantment and secularization, resulting in political autonomy, irreversible.

Gauchet's view does not imply that religion has become impossible. His claim is that religion has lost its key role in the level of public society, and will never be able to reclaim that position. Nor does Gauchet assert that the ongoing development of autonomy will result in a world without heteronomy. On the contrary, since heteronomy is a structural feature of the human being, it will continue to be part of our human experience, but it need not take the form of religion.

Taylor is more prudent in his considerations about the public role of religion in the future. In his *opus magnum* on secularization, *A Secular Age*, he describes the vicissitudes of religion as a 'zigzag account,' to be opposed to linear theories about the gradual decline of religion in human history. His purpose is not to describe secularization empirically, be it as the decline of religion in the public sphere ('secularity 1') or as the decay of personal religious beliefs ('secularity 2'). Rather he wants to offer a cultural analysis on the transcendental level: which conditions made it possible for Western culture to evolve from a clearly religious age around AD 1500 to a secular age in our times?

According to Taylor, one cannot tell a linear 'subtraction story' about, for instance, science and religion, where science is held to make religion obsolete by taking over its truth function. Such subtraction story argues that once science has displaced religion as the center of knowledge about the universe, the true nature of human existence is finally revealed, and it has nothing to do with religion.

Taylor chides this simple picture for two reasons. First, the subtraction story of positivism, scientism, or new atheism ignores the essential role of religious transformations in the genesis of modern science. The history of religion proves that religion is itself capable of rationalization (the Weberian thesis). For instance, the axial period of religious history, constituting a revolution along rational and ethical lines, raises questions as: how can the Gods behave as capriciously as human beings? How can good and evil be mingled in a divine nature? Later on, the period of Protestant Reform (sixteenth century) inaugurated what *Michel Foucault* has called the 'disciplinization' of culture. This new culture of discipline certainly contributed to the rigid methods of modern science.

Second, religion and science are not inversely proportional quantities. Religion also benefited from the new culture of discipline, self-reflectivity, and austerity. In the nineteenth century and the first half of the twentieth century, Christianity competed with socialism and liberalism for the soul of the supposedly enlightened individual. Religion probably never thrived to a similar degree as in this 'age of mobilization.' It is just one example of why the story of secularization is rather a zigzag account than a linear development.

Although Taylor's and Gauchet's genealogies of modernity and secularization broadly converge on an empirical and transcendental level, their ways part when it comes to their appreciation of secularization and modernity. Gauchet's linear story

logically results in his thesis about the irreversibility of secularization in the public sphere. Taylor's zigzag account also 'logically' leads to the opposite thesis. With Bellah (and Hegel), Taylor believes that 'nothing is ever lost.' A certain historical epoch has always inherited a lot from and was always made possible by previous eras. The historic sediments of foregone ages may always be dug up again, and may provoke us to criticize our contemporary ways of living. Hence, Taylor believes that with the high degree of discipline that dominates our culture, we tend to lose sight of religious, festive, and communal forms of life. It is by no means predictable which road the future will take: will our society eventually ban all reference to religion, or will it rediscover the richness of the religious past?

Bellah's dictum that 'nothing is ever lost' also echoes, be it inadvertently, in much of contemporary deconstructionist philosophy. *Jean-Luc Nancy*, for example, develops in *La déclosion* (2005, Engl. transl. 2007) a deconstruction of Christianity that draws attention to secular elements inherent to Christianity – which ultimately is a religion of self-deconstruction. Since the secular is essentially a product of monotheistic religions, it can never be fully understood without reference to religion. Hence, it is precisely religion that withstands any full definition of 'the secular.'

A Secular or Post-Secular Age?

Given that the once hegemonic status of the classic secularization paradigm is under fire, not only outside the West or in North America, but even in the heartlands of the classic secularization paradigm, Western Europe, it is no coincidence that the German philosopher Jürgen Habermas coined the term 'post-secular.' Over the course of the past decade, that very term has gained acknowledged currency. It seems to imply that we are experiencing a new era, by leaving behind our secular existence and simultaneously rejecting, on a theoretical level, the once dominant secularization theory.

However, the concept 'post-secular' (as coined by Habermas and many others) is not neutral. Actually, it presupposes a classic interpretation of the term secular, that is, as a narrative in which secularization is synonymous to the disappearance of religion (Habermas, 2005).

As already mentioned, a significant number of sociologists and philosophers currently dispute that classic presupposition. That is, for instance, the central reason why Taylor refuses to use that very term in *A Secular Age*. Only once does he make use of the term, when referring to the situation in 'post-secular' Europe (Taylor, 2007, pp. 534–535). Taylor's alternative master narrative in *A Secular Age* argues, first, that religion has not disappeared in the secular age, but that it has become more fragile, an embattled option among other options. Second, he claims that we have become secular due to the rise of a self-reflexive concept of the subject precisely inaugurated by religion (cf Gauchet, 1997), and that (contra Gauchet, 1997), therefore, a secular society has never been completely devoid of religion but that religion has remained vital and has produced ever more diverse forms of self-experience and self-reflective attitudes, that is, vicarious forms of and approaches toward religion. In other words, "Charles Taylor can be read as arguing that only a good secularist can be a good Christian, and only a Christian can be a good secularist." (Mendieta in Gorski et al., 2012, p. 308)

This controversy around the concept 'post-secular' is strongly related to the problem of the place of religion in the public sphere and the role of religious vis-à-vis secular language (Mendieta and VanAntwerpen, 2011). Exclusionists take the position that only secular arguments and motives count in the public debate and that, consequently, religious argumentation has to be excluded (Audi, 2000). Inclusionists claim that there is no need for a proviso, even not regarding the possibility that a religious majority can take public decisions, legally legitimized, on the basis of pure religious argumentation. (Weithman, 2002; Audi and Wolterstorff, 1997). Habermas, Rawls, and Taylor take mid-positions between those of exclusionists and inclusionists, albeit from different interpretations of the concepts of the 'secular' and the 'post-secular' (Rawls, 2001; Habermas, 2008; Mendieta and VanAntwerpen, 2011).

Secularization: The West versus the Rest

Whether one designates our contemporary age as 'secular' or as 'post-secular,' the growing sensitivity for the complexity of the concept of secularization in the Western world is even intensified, when it is transferred to non-Christian religions and to other areas in the world. The case of India is especially instructive in this regard. Since its independence from Britain, secularism has been a defining feature of its political system, whereas at the same time, it has become a deeply contested concept. A whole gamut of scholars claim that Western secularism, imposed on Indian society as a hegemonic ideology indebted to Protestant Reformation, is not viable for Indian society. They argue that minority rights for the traditional believers and religious toleration offer a more reliable guarantee for ethnic and religious tolerance than secularism does. In a similar vein, analogous questions and controversies apply to the worldwide problem of migration in general and of Muslim migration in Europe in particular (Gorski and Altimordu, 2008, pp. 72–73; Bhargava, 1998).

In order to cope with the difficulty of finding a concept covering the worldwide relations between religion and contemporary societies, the classic category of secularization hardly seems to be applicable. Since religions such as Confucianism or Taoism, for instance, have, in a sense, always been 'wordly' and 'lay,' the Western concept of secularization does not make much sense as a descriptive account of their recent evolution (Casanova, 2006, pp. 12–13). Therefore, a number of scholars (Eisenstadt, 2003; Casanova, 2006; Taylor, 2007) have developed the concept of 'multiple modernities' as a more adequate tool to designate global trends in this respect compared to either secular or post-secular cosmopolitanism or a clash of civilizations between religious and secular regimes (Casanova, 2006, p. 13).

Those who support this 'multiple modernities' position reject both the position of a modern radical break with religious traditions (classic or neoorthodox secularization paradigm) as well as the position that defends an essential continuity with tradition. Traditions are forced to adjust to modern conditions, in the process of which they also help to shape the particular forms of modernity (Casanova, 2006, p. 14).

The lively discussion about topics like 'multiple modernities' and the relation between 'secular' and 'post-secular' shows that the original self-evident belief in the inevitable decline and eventual extinction of religion has made room for a versatile debate not only around a whole gamut of specific aspects of the relation between modernity and religion, but even for a renewed conceptual analysis of the term 'secularization' itself: "Which is to say that the definition of the secular and its relationship to the religious are as hotly disputed now as ever, and that the scope of the debate is probably wider than ever. Whether this period of contestation marks the beginning of a post-secular age, or merely a period of secular ebb and religious flow, only time will tell." (Gorski and Altimordu, 2008, p. 77).

Securitization

Philippe Bourbeau, University of Cambridge, Cambridge, UK

Abstract

Securitization is one of the most dynamic fields of research in today's security studies. This article (1) examines the various definitions developed by scholars to make sense of the phenomenon, (2) presents the two logics upon which most of the research is conducted (i.e., the logic of exception and the logic of routine), and (3) identifies avenues of research that will most likely drive future research in this field.

Securitization is one of the most dynamic fields of research in today's security studies. Several sets of arguments, factors, rationales, and explanations have been offered to better understand and explain mechanisms of securitization. Constructivists, postmodernists, political sociologists, neoliberalists, critical theorists, feminists, and normative theorists are all participating in the debate. This article is divided in three parts. First, I will examine the various definitions of securitization currently proposed by scholars. The second section will analyze the major line of cleavage among theorists of securitization, i.e., the logics of securitization. Finally, I will seek to identify future avenues of research that although by no means exhausting the possibilities will most likely drive most of the research in years to come.

Definitions of Securitization

If scholars find it hard to reach a consensus on a definition of security, they find it equally difficult to agree on a definition of securitization. A first definition was proposed by Ole Wæver (1995) in his seminal paper in which he argues that security is an intersubjective and socially constructed process and that security is about survival. Securitization seeks thus to understand the processes by which "an issue is presented as posing an existential threat to a designated referent object." In that sense, securitization studies aim to gain a better understanding of "who securitizes, on what issues (threats), for whom (referent objects), why, with what results, and, not least, under what conditions" (Buzan et al., 1998: p. 31).

This definition of securitization is contested. In the same year of the publication of Barry Buzan, Ole Wæver, and Jaap de Wilde important book, Didier Bigo proposed a different take (the paper was first published in French in 1998 and then translated into English in 2002). Focusing on the issue of migration, he argues that "the transformation of security […] is directly related to [security professionals] own immediate interests […] and to the transformation of technologies they use […]. The Europeanization and the Westernization of the logics of control and surveillance of people beyond national policies is driven by the creation of a transnational field of professionals in the management of unease. This process of securitization is now well known" (Bigo, 2002: p. 64).

Influenced by the work of Bigo, Thierry Balzacq (2005: p. 172) proposed another definition a few years later. In an important contribution to this field of research, he argues that securitization is "a strategic (pragmatic) practice that occurs within, and as part of, a configuration of circumstances, including the context, the psycho-cultural disposition of the audience, and the power that both speaker and listener bring to the interaction." Balzacq has recently slightly modified his definition of securitization in proposing a short and a long definition. For him, securitization is, "a set of interrelated practices, and the processes of their production, diffusion, and reception/translation that brings threats into being" and "an articulated assemblage of practices whereby heuristic artefacts (metaphors, policy tools, image repertoires, analogies, stereotypes, emotions, etc.) are contextually mobilized by a securitizing actor, who works to prompt an audience to build a coherent network of implications (feelings, sensations, thoughts, and intuitions), about the critical vulnerability of a referent object, that concurs with the securitizing actor's reasons for choices and actions, by investing the referent subject with such an aura of unprecedented threatening complexion that a customized policy must be undertaken immediately to block its development" (Balzacq, 2011: p. 3).

Building on these definitions, I have proposed to understand securitization as the process of integrating discursively and institutionally an issue into security frameworks that emphasize policing, control, and defense (Bourbeau, 2013b). Whereas the discursive element of this definition refers not only to the use of language but also to practices associated with language, the institutional dimension refers to notions of acceptance and the mechanisms of endurance, path dependence, and continuity in socially constructing issues as security ones.

Despite these disputes regarding definitions of securitization, the main objectives of securitization scholars remain to better understand and explain this particular social process. For that purpose, scholars have mainly proposed two logics of securitization.

Logics of Securitization

As currently organized, the literature on the securitization process rests mainly on two logics: the logic of exception and the logic of routine. These logics should not be viewed as opposing ones, as they are not competing views. In fact, it is not at all clear that they can compete, for it is not clear that they are mutually exclusive.

Building primarily on the work of Carl Schmitt, the logic of exception postulates that security is about the fight against an existential threat that necessitates exceptional measures. It focuses on speech acts legitimizing exceptional policies and practices in the face of an existential security threat. The so-called Copenhagen model (or school) best illustrates the logic of exception and has become over the years the current benchmark in securitization research (Buzan et al., 1998; Wæver, 1995). Bringing speech act theory into security studies, the Copenhagen model posits that labeling something as a security issue permeates it with a sense of importance that legitimizes the use of emergency measures outside of the usual political processes to deal with it. It is by labeling a phenomenon a security issue that it becomes one.

The model distinguishes two types of actors: a securitizing actor securitizing issues by declaring something existentially threatened and a functional actor affecting the dynamics of a sector. Securitizing agents do not navigate freely toward successful securitization. In fact, "conditions for a successful speech-act fall into two categories: (1) the internal, linguistic-grammatical – to follow the rules of the act (or, as Austin argues, accepted conventional procedures must exist, and the act has to be executed according to these procedures); and (2) the external, contextual and social – to hold a position from which the act can be made" (Buzan et al., 1998: p. 32). On top of these facilitating conditions, the Copenhagen model argues in a bold statement that "discourse that takes the form of presenting as an existential threat to a referent object does not by itself create securitization – this is a securitizing move, but the issue is securitized only if and when the audience accepts it as such … successful securitization is not decided by the securitizer but by the audience of the security speech-act" (Buzan et al., 1998: p. 25).

In the past decades, the Copenhagen model has provoked heated debates and has captured the attention of an increasing number of scholars: Articles analyzing the model's strengths and weaknesses have been published as leading article in major international relations journals, and panels have been organized at several annual conventions of the International Studies Association. While most security studies theorists disagree with at least one aspect of the Copenhagen model, they nearly all recognize that this particular take on the securitization process is one of the most creative, rich, and stimulating models in today's security studies.

Debates about the Copenhagen model have evolved through several interrelated phases, and major lines of criticisms have touched on several elements of the model. Scholars have criticized the model for fixing collective identity and have questioned the responsibility of the analysts in studying security. Others have focused their criticism on the speech act theory and its applicability to security studies arguing that the model underestimates other powerful practices such as the production of image and the use of symbols (Hansen, 2011; Williams, 2003) or that the model fails to include other categories or types of acts (Balzacq, 2005; Huysmans, 2006; Vuori, 2008). Scholars attuned to poststructural and gender perspectives have underscored that the model failed to take into account the silenced voices (Hansen, 2000). Others have argued that the model left the audience significantly under-theorized (Balzacq, 2005; Salter, 2008). Whether the model can include the issue of context in its framework has been analyzed (Bourbeau, 2011; McDonald, 2008; Stritzel, 2007). Others have focused their criticisms on the lack of universal and transcultural understanding of "the established rules of the game" (Curley and Wong, 2008). Still others have argued that the Copenhagen model, as currently organized and applied, cannot explain variation in levels of securitization and that it presents a thin understanding of the concept of power, particularly the power of contextual factors – which should be understood as the power to enable and/or constrain securitizing agents (Bourbeau, 2011).

In contrast, the logic of routine inspired by Michel Foucault's and Pierre Bourdieu's systems of thoughts sees securitization as a process of establishing and inscribing meaning through governmentality and practices. It understands the securitization process as routinized and patterned practices, particularly bureaucracies' and security professionals' practices, in which technology comes to hold a prominent place. The logic of routine comprises a broader set of security scholars than for the logic of exception. Each scholar brings to the table his own focus and influences, and although the logic is far from consistent across scholars, it cannot be ignored either.

Bigo is a central figure of the logic of routine. He argues that security is not necessarily about survival nor is it about urgency and exceptional measures. Rather, security is largely defined by mundane bureaucratic decisions and practices that create a sense of insecurity and unease. Using Bourdieu's concepts of field and habitus, Bigo contends that the field of insecurity while breaking the traditional internal–external understanding of security absorbs other fields, and in doing so produces a security continuum in which various agents come to interact under the umbrella of this field. Focusing on the case of migration, Bigo argues that the securitization of immigration emerges "from the correlation between some successful speech acts of political leaders, the mobilization they create for and against some groups of people, and the specific field of security professionals […] It also comes from a range of administrative practices […] and what may be termed a specific habitus of the 'security professional' with its ethos of secrecy and concern for the management of fear or unease" (Bigo, 2002: p. 67). Bigo's work has been very influential, and several scholars have developed and further expanded his set of arguments.

Following in these footsteps, Balzacq has recently argued that the securitization process is better understood as a strategic (pragmatic) process occurring within, and as part of, a configuration of circumstances in which context, audiences, and power relations play an important role. For him, security performatives are situated actions mediated by agents' habitus. Seeking to "reformulates the assumptions of securitization in a form appropriate to empirical studies and to the development of a comprehensive theory," Balzacq (2011: p. 1) proposes three core assumptions: the audience is central in the securitization process, the agent and context are codependent, and the *dispositif* connects different practices.

The logic of routine has so far been subjected to less critical engagements than the logic of exception (and particularly the Copenhagen model). Yet, friendly criticisms are starting to emerge. Michael C. Williams (2011), for example, argues that if

security is defined away from an explicit logic of extremity, then there is a danger that it will become difficult to distinguish any number of policy changes from ones that specifically relate to security. He further points out that "while the language of emergency can appear an obstacle to more theoretically nuanced and empirically grounded understanding of concrete practices, it may at the same time provide an anchoring device through which 'security' dynamics can be discerned and distinguished from 'normal' change with the policy process" (Williams, 2011: p. 217). Elsewhere, I have criticized the logic of routine for its understanding of who can be a securitizing actor and for offering very little guiding principles in explaining variation in levels of securitization (Bourbeau, 2014).

Future Avenues of Research

The nature, mechanisms, contours, and consequences of the securitization process are one of the most active and fast growing areas of research of global politics. Undoubtedly, there is substantial disagreement among scholars that this short article cannot fully engage with. Yet, future avenues of research (or of disputes) can be divided into four broad categories: the politicization versus the securitization process, the issue of methods in securitization research, the various strategies of contesting security, and varieties of issues under investigation.

The Politicization versus the Securitization Process

Distinguishing between the politicization process and the securitization process is an important step in our study of contemporary security politics. There is substantial disagreement as to whether the two processes are in fact distinct. Arguments on both sides of the spectrum have been put forward: from the somewhat radical position that security is in fact placing an issue beyond normal politics to the equally radical position that security is the normal politics. Yet, highlighting the importance of distinguishing the two processes does not mean that there is no politics in the securitization process. To take international migration as example, it is one thing to question the refugee determination process or the adequacy of immigrant settlement services or the over-concentration of immigrants in large cities. It is an altogether different one to argue that international migration is a national security threat to a given society or a state.

In an effort to stimulate a richer dialogue between the literature on the politicization process and the literature on the securitization process, I have recently put forward the argument that the two processes are two distinct processes but they are not mutually exclusive, for it is not clear that they are competing forces (Bourbeau, 2013a). Several hypotheses could guide future research: Can a negative politicization of an issue induce the securitization process, idiosyncratically as well as over a longer time period? Does a negative politicization necessarily lead to the securitization? Does the relationship between the two is a question of intensification: The more 'intense' the politicization is, better are the chances that it will become a security issue? If so, what is the threshold and how do we recognize it?

Williams (2012) has been one of the first to propose the intensification hypothesis. He argues that the concept of intensification may hold some promise as a means of moving beyond the division between scholar attuned to the logic of exception and advocates of a pragmatic-routine approach. Normal politics, unease, and thresholds could be seen as forms of intensification below extremity. Yet, the idea of a fundamental breaking of rules remains central to security analysis, argues Williams, precisely because it provides a much-needed limit condition.

Methods

How do we know when an issue has been securitized? This seemingly simple question constitutes one of the thorniest issues in contemporary security studies. This is best exemplified with the case of international migration. Some almost take it for granted; others strive to explain the securitization of migration without first demonstrating whether migration is securitized or not – either globally or in the country/cases under investigation. As a result, contradictory standpoints have been presented with little methodological consensus on which to build on. Indeed, whereas the majority of scholars have argued that migration has been successfully securitized in most OECD countries, others, on the contrary, have found little evidence to the effect that migration was securitized in Europe.

The literature is slowly making steps in correcting this situation, however. Two paths out of the wood can be identified. A first one is to better understand the phenomenon under study. In my comparative analysis of the securitization of migration in Canada and France, I have offered two categories of indicators to gain a better understanding of whether migration is securitized (and to what extent) or not in Canada and France. Both sets of indicators offer nominal and ordinal measurements (Bourbeau, 2011).

The first category is institutional indicator, which includes whether immigration acts mention in one way or another security provisions or not and whether official policy statements that relate to security, foreign affairs, and defense discuss immigration in security terms or not. To illustrate, whereas the previous official statement entitled *Competitiveness and Security: Direction for Canada's International Relations* published in 1985 was silent about the issue of international migration, the statement *Foreign Policy Themes and Priorities* issued in 1991 listed migration as a security threat to Canada. The inclusion of migration as a security concern was reiterated in the *White Paper on Defence* of 1994, *Canada in the World* statement of 1995, *Securing an Open Society: Canada's National Security Policy* of 2004, and *Canada's International Policy Statement* of 2005. The second category of indicators is security practices, which include interdiction policies and detention of immigrants. Using this broad range of indicators, Bourbeau demonstrates that migration is securitized in both Canada and France and that significant variations exist between the two country cases on the level of securitization, thereby opening up research possibilities to study the variation.

Indeed, the question of variation in securitization is a rather underdeveloped and undertheorized one in the literature. This might be because most of the empirical studies are case study and

not small-n or large-N comparative analysis. This fact remains that too few contributions try to make sense of the differences in levels of securitization (for example, between a thick/strong/high securitization and a thin/weak/low securitization – regardless in fact of the exact vocabulary one uses). Is it a question of number and/or strength of securitizing moves or degrees of reception by audiences (broadly defined)? If we accept Bigo's central argument that the habitus of the security professionals is the key driver of securitization, then does a variation in 'strength' of security professionals across cases explain a variation in levels of securitization? The more powerful security professionals are, the ticker/harder/stronger securitization we observe? Extending Williams' work (2012), is a variation in securitization a question of intensification? My comparative analysis offers guiding principles to account for the variation in the levels of securitization; I suggest that contextual factors, particularly when their power is understood as the capacity to enable and/or to constrain, offer a promising axiom of research into the issue of variation (Bourbeau, 2011).

A second option is to focus on methods of investigation of the securitization process. Attuned to comparative politics stress on the research design, I employ the logic of triangulation by which findings obtained with one research method are contrasted against findings obtained with another method (Bourbeau, 2011). Using a broad range of methodologies (from content analysis, to statistical analysis, to interviews, to surveys and polls) has proved successful in providing a high level of robustness to his study. Balzacq (2011) has also recently ventured into these method questions, albeit from a slightly different perspective and with a different set of questions in mind (and not necessarily in terms of international migration). He proposed to distinguish between four methodological techniques of securitization research: discourse analysis, ethnographic research, process tracing, and content analysis. Stefano Guzzini (2011) has also recently suggested a stimulating path: to use the idea of 'securitization' as a causal mechanism in process tracing and interpretivist methodology.

Despite these contributions, the literature on the securitization process remains overly theoretical with few comprehensive empirical studies within case across time and/or across cases. To fully establish itself as a dynamic and important area of research, securitization research will have to make inroads in better understanding to what extent an issue has been (or not) securitized and it will have to diversify its methodological techniques from the already well-covered content analysis and discourse analysis to small-n comparative analysis and even large-N statistical analysis.

Strategies of Contesting Securitization

What are the options for those wanting to contest a successful securitization? For a long time, scholars focused almost exclusively on one strategy: desecuritization. Initially conceptualized as somewhat the opposite of securitization, desecuritization quickly became a subject of disputes in security studies. The Copenhagen model understands desecuritization as the process of taking an issue out of the security/emergency mode and bringing it into the political sphere. Huysmans (1998) has proposed to see it as the unmaking of securitization. By the mid-2000, several scholars focused their attention on this apparently twin concept of securitization. Claudia Aradau's (2004) stimulating article has made important steps in debunking the meaning of desecuritization and has spurred an enriching dialogue on the question. She criticized the literature on desecuritization for tackling the issue analytically (and for doing so in vague terms), thereby eschewing that desecuritization is about politics and the type of politics we want. Rita Floyd (2011) has argued that desecuritization is not morally better than securitization. Paul Roe (2012) has recently revisited the normatively defined debate over securitization as a negative concept. In a superb contribution, Lene Hansen (2012) has defined desecuritization as the move of an issue out of the sphere of security and has proposed to recover the political status of desecuritization through four readings of desecuritization: (1) as a Derridarian supplement to securitization, (2) as a way of 'reworking' the friend/enemy distinction, (3) as an emphasis on responsibility and choice, and (4) as an illustration of the particular historical context of Cold-War détente.

Yet another strategy of contesting successful securitization is resilience. In recent years, a great deal has been written about the role of resilience in our social world. This scholarship has sparked vivid theoretical debates in psychology, criminology, social work, and political geography about the nature of resilience and how scholars should go about studying it. Security studies are a latecomer in the field, and while the term is sometimes employed, it is rarely debunked and theorized. Balzacq's (forthcoming) edited book takes important steps in correcting this. Resilience is one of the four strategies of contesting security he identified (the others are desecuritization, resistance, and emancipation). In addition, I suggest a theorization of resilience as applied to the securitization process in which he argues that current definition of resilience (as the positive adaptation within the context of significant adversity) is problematic because it eschews that resilience has a dark side and that it is always a matter of degree (Bourbeau, 2013b).

Going beyond Migration, Environment, and Global Health

Although most of the conversation has been done in theoretical terms, extensive empirical studies of the securitization process have been conducted mostly in the field of migration, environment, and health. Scholars have in fact conducted research on the migration–security nexus within case across time, across cases, and on almost all continents. A large strand of this literature was part of migration studies' focus on whether and to what extent the nation-state remains capable of regulating and controlling international migration. Other scholars have emphasized the effects (usually negative) of the securitization of migration on migrants themselves: some highlighting the interconnections of security practices and human rights considerations, others hypothesizing that the securitization of migration is the latest and most modern form of racism.

Environmental and energy security has also attracted the attention of several scholars. For some, the case of environment underscores the limit of the logic of exception and illustrates the need to adopt alternative approaches. Others have employed the environmental case to demonstrate the analytical strength of the Copenhagen model and to propose

a refined version of it (Floyd, 2011). Global health issues have also recently a fair amount of attention by scholars of the securitization process. Key issues include HIV/AIDS, SARS outbreak, and Asian influenza. One of the central questions that have driven most of the analysis is whether (and to what extent) these global health should be framed as security issue. Some have argued that although framing AIDS as an international security issue could raise international awareness and resources, it also runs the risk of pushing responses away from the civil society toward military and intelligence organizations (Elbe, 2006). Others have argued that domestic, political, and social context within states are the key drivers of responses to infectious disease in contrast with international discourse of health security, thereby making an important step in understanding the policy challenges of implementing the global discourse of infectious disease securitization at the domestic level (Curley and Herington, 2011).

Other nontraditional security issues need to be further studied, and some scholars have started to make inroad in this regard. Although cybersecurity, critical infrastructures, and securitization as a mechanism of the democratic peace have received insufficient attention so far (Hayes, 2012), they will most likely be at the center of several debates in securitization research for years to come.

Abstract

This article outlines the legal framework within which debtors use their assets to secure payment or assure the performance of their obligations to their creditors. It analyzes the range of security interests recognized in major legal systems, starting with their development under Greek and Roman law. It then focuses on the modern position, drawing on the English Common Law as well as the French and German Civil Codes. It also describes a discernible trend toward a more functionalist approach, originating in Article 9 of the US Uniform Commercial Code. It concludes by placing the legal position in its economic context.

Introduction

Security Law, often also described as Secured Transactions Law, forms part of a legal jurisdiction's commercial law regime. It deals with interests in property that are created by way of security for payment or performance of an obligation. Although typically capable of securing any obligation, they are often given by borrowers to creditors in order to secure repayment of debt.

In lending transactions Security Law enables the provision of credit, in the knowledge that it may, in case of the borrower's default, be recovered through recourse to the borrower's property, which may be sold or otherwise dealt with, in order to recover the monies owed. The direct access to the particular property conferred by the security interest generally enables the lender to enforce the claim without first having to expend time and money in obtaining a court judgment. Most importantly, the lender's legal status as a secured creditor may in many legal jurisdictions confer protection in the event of the borrower becoming insolvent, enabling the secured creditor to realize the security rather than initiate insolvency proceedings. Lenders therefore frequently make the provision of security a prerequisite for the advance of a loan.

Security Law intersects with other areas of law, including contract law governing the underlying loan and security agreement; property law facilitating dealings with particular assets; and insolvency law impacting on the payment of creditors. Its operation is generally a matter of domestic law, with its scope and application in any legal jurisdiction depending on the rules of that jurisdiction. Historically, security law jurisdictions have been classified into three main groups: those of Anglo-American Common Law countries; Napoleonic civil law countries based on the French Civil Code; and Romano–Germanic countries based on the German Civil Code (Wood, 2007). Since the 1950s, however, American jurisdictions have adopted a broader functional approach to determining the scope of security interests; an approach whose influence has now begun to spread internationally and cut across some of the traditional groupings.

This article is divided into six sections. The first section outlines traditional features of security interests. The next section examines their early development under Greek and Roman law and is followed by an analysis of their current operation under the English Common Law regime and under the French and German Civil Code frameworks. The penultimate section describes the functionalist approach to Security Law and the final section places the legal discussion within its broader commercial context, emphasizing the economic importance of Security Law.

Security Interests

'Security interests' is the collective term used to describe a range of interests in property which secure the performance of an obligation. The term 'interest' refers generically to the various bundles of rights that make up particular types of interest.

Security interests may arise by operation of law. Common examples are liens where, in special circumstances, property can be detained for the satisfaction of an obligation. This article focuses, however, on consensual security interests, arising from negotiation between debtors and their creditors. Traditionally they fall into two fundamental categories identified by reference to whether the creditor must necessarily have possession of the property for the security to be enforceable. As the description implies, possessory interests require a creditor to have possession of the borrower's property. By contrast, nonpossessory interests may arise from, for example, a transfer of ownership to the creditor or the creation of some form of encumbrance over the borrower's property in favor of the creditor. In economic terms, the latter are the more important interests.

It is the creation of the actual interest in the property that distinguishes security interests from arrangements such as guarantees. Although guarantees are often commercially considered to constitute security, they are in legal terms merely contractual promises to make payment in specified circumstances. They do not of themselves confer an interest in property, although guarantors may choose additionally to give security in order to support their promise.

Typically, a security interest is created through the borrower granting the creditor a specific interest over property which the borrower owns. There are nonetheless transactions which resemble security but which legal regimes often do not recognize as part of their security law because they do not involve any grant by the borrower. The classic example is a reservation

of title (ownership) arrangement under which a vendor provides credit to a purchaser by permitting the purchaser to take possession of goods on terms that ownership to those goods will not pass until the purchaser makes full payment to the vendor. In such circumstances, there is no grant of an interest. Rather, the vendors reserve their own interest of ownership, thereby protecting themselves against nonpayment by the purchaser. Some legal jurisdictions which adopt the functional approach and focus on the economic substance of the transaction rather than its form have, however, explicitly brought reservation of title arrangements within their security law (see Functional Approach below).

Assets capable of being given as security (sometimes described as 'collateral') commonly include land as well as other property. Within this latter broad category is not only property which has a physical manifestation such as plant and equipment and motor vehicles but also property which is intangible, such as debts. Jurisdictions often develop different rules relating to security over land and security over other types of property, a consequence of the historical importance of land as a source of wealth and, more generally, its unique attributes. Jurisdictions may also provide special regimes for specific types of collateral (such as cash and financial instruments) important for the stability and efficiency of financial markets (Gullifer, 2008).

A modern security law regime is expected to provide mechanisms not only for the valid creation of a security interest in property but also for determining the priority of competing security interests and the availability of remedies to enforce the security interests in the event of default.

Graeco–Roman Origins

The development of security law has a long history and emerged as part of the creation of ownership-based societies in many parts of the ancient Mediterranean and ancient Near East (*see* Property Rights). References to security can be traced back to the earliest legislation of the Greek *polis*. When Solon, appointed as the ruler and lawgiver of Athens in 594/3 BC, canceled existing debts as part of his famous legal and economic reforms, this was signified by the removal of *horoi*. These were slabs of stone, marking the encumbrance of land as part of a loan (Finley, 1981). Approximately 250 *horoi* have been uncovered and documented. They date roughly to the period of 400–200 BC, which indicates their widespread and continuous use (Millett, 1985). One example is a marble block found within the city of Athens that reads: 'Horos of a workshop hypothecated, 750 (drachmas)' (Finley, 1951: 4).

Three distinct types of security appear on the *horoi: hypotheke, prasis epi lysei*, and *apotimema*. Of the three *prasis epi lysei*, ('sale on condition of release', Finley, 1951), was the most frequent, with 65% of *horoi* disclosing an encumbrance of this type (Millett, 1985). The property in question was 'sold' to the creditor, but on the condition that it would be 'released' or reconveyed on repayment of the loan. The debtor as a rule retained possession. It has been assumed that on default, the creditor acquired unrestricted ownership of the property and could take legal action if the debtor refused to transfer possession. *Prasis epi lysei* was regarded as the typical form of real security in ancient Athens (Harrison, 1968).

While the concept underlying *prasis epi lysei* is that of sale, the term *hypotheke* signifies the 'object put down' (Finley, 1951: 29). Only 5% of *horoi* refer to this type of security. Little evidence is available to distinguish *hypotheke* from *prasis epi lysei* transactions. It has been suggested that the *hypotheke* was a more flexible instrument. There is evidence that it was more often used in conjunction with written contracts (Finley, 1951). The absence of any reference to 'sale' suggests that ownership stayed with the debtor (Harrison, 1968). The concepts of ownership and possession were, however, less developed in Athenian law than in Roman law. Hence assumptions in relation to 'ownership' require qualification (Lipsius, 1915; Harrison, 1968). Under the *hypotheke*, the 'owner'–debtor also retained possession (Finley, 1951).

The remaining 30% of '*horoi*' identify the third type of security – *apotimema*. *Apotimema* was classified as either *pupillary apotimema* or *dotal apotimema*. The former signified a security transaction where an orphan's estate was leased out under the state's supervision and a *horos* was placed on the property of the lessee as security for the return of the lessor's property. The latter ensured the return of the dowry to the father of the bride in the case of divorce or other circumstances. It is clear from the nature of *apotimema* transactions that the party providing the security remained in possession of the property (Finley, 1951).

Two other important forms of Greek security transactions related to movables. The first was the *enechyron* (pledge), where movables were handed over to a creditor as security for loans. There are instances of Greek orators handing over gold cups, horses, slaves, and gold crowns to creditors, including bankers (Harrison, 1968). The second took the form of maritime or bottomry loans where the ship master or merchant obtained an advance of money on the security of the ship, the slaves who formed its crew, or its cargo (MacDowell, 1978).

The taking of security was also a 'universal feature of Roman life' (Crook, 1967: 243) and was critical in an economy based on debt (Harris, 2008b). It was in Rome that the law of security was developed into a system and codified. This codification, in turn, became the model for modern security law.

The Roman law *fiducia* (*fiducia cum creditore contracta*) provided that the ownership of property was formally transferred (through *mancipatio* or *in iure cessio*) for security purposes to the creditor, who agreed to reconvey the property on repayment of the loan. The transfer of possession from the debtor to the creditor was not required to make this transaction effective. Typically the debtor was left in possession. This type of security applied to *res mancipi*, i.e., property the ownership of which could formally be transferred to the creditor. It included the most important Roman asset classes such as land, slaves, cattle, horses, mules, donkeys, and rights of way and of water. However, the debtor retained a right against the creditor, the *actio fiduciae*. This precluded the creditor from selling or encumbering the assets, and obliged the creditor if in possession, to prevent any damage. If the loan was not paid back when due, the creditor could seek compensation from the property securing the loan. Contracts typically contained a clause allowing the creditor to sell the property (for example, the standard contract – *Formula Baetica* – found in a notary's office in Spain and tablets from Herculaneum, see Crook, 1967). If the sale proceeds were less than the loan obligation, a residual obligation on the part of the debtor remained. On

the other hand, if the sale proceeds exceeded the obligation arising from the loan, the excess (*superfluum*) was owed to the debtor (Kaser, 1971).

The Roman law *pignus* allowed the creation of a security interest without any formal transfer of ownership. This is believed to have originally required the delivery of the property to the creditor. However, from the third century BC a *pignus* was already capable of use as a nonpossessory security interest by agreement, without delivery of the property. *Pignus* without possession was also referred to by the Greek term *hypotheca*, although there is no direct evidence suggesting that it was introduced due to Greek influence (Kaser, 1971). If the property was delivered to the creditor, the use of the property by the creditor required permission from the debtor. Similarly, the creditor had no automatic right to take the profits and fruits of the property. This also required an agreement with the debtor, and the value of fruits and profits were typically offset against interest and loan principal ('Anticresis', Kaser, 1981).

Property that could be subject to a *pignus* included all physical things, obligations (*nomina*), and anything else saleable. A flock or a herd could be subject to a *pignus* even though the individual animals might change. Similarly, ungathered fruits or unborn animals, and children were also so subject (Roby, 1902). Moreover, a *pignus* could be created over the whole of a debtor's property, including all the debtor's current and future assets (Kaser, 1971). Similar to the *fiducia*, loan contracts regularly stipulated that the creditor would sell the asset used as security, should the loan agreement not be fulfilled when due. The debtor was entitled to any excess of the sale proceeds over and above the obligations arising from the loan. At its fullest stage of development, the *pignus* provided the creditor with the *Actio Serviana*, a special (praetorial) legal action that allowed a creditor to obtain possession of the property used as security from the debtor or any third party if a debt was not paid when due (Kaser, 1971; Jolowicz and Nicholas, 1972).

Roman creditors, who held security interests, also retained priority over unsecured creditors when execution was levied against an insolvent debtor's assets (Kaser, 1996).

English Common Law

Common Law developed in medieval England as the law common to the whole of the country and has become the generic term used to describe the English legal system as well as those legal jurisdictions which adopted a similar legal framework, whether historically through colonization or otherwise. The Common Law classification of security interests into mortgages, possessory securities, and hypothecations has been traced to Roman Law, although significant differences developed in their operation (Sykes and Walker, 1993).

Three types of consensual security interests, reflecting the above classification, are generally recognized in relation to personal property under Common Law: the pledge, the mortgage, and the charge (Beale et al., 2012). Such interests are commonly given by the person who owes payment or the performance of a particular obligation that is secured by the asset. Underlying personal liability on the part of the debtor is not, however, a necessary criterion. A third party may give any of the security interests, to support a promise made by a debtor to a creditor.

Common law classifies property and interests in property by reference to whether they are 'legal' or 'equitable'. This reflects the historical development and recognition of property and interests by courts exercising what is described as 'Common Law' or 'equitable' jurisdiction. The classification remains important in the context of security law as it can impact on the type of security that can be taken over particular property as well as on the operation of priority rules and the availability of remedies.

A pledge, a very early form of security (Goode, 2010), is created by a person (the pledgor) giving possession of an object to a creditor (the pledgee) by way of security, on the basis that the creditor will return the object on payment of the debt. In the event of a default, the pledgee may sell as agent of the pledgor. The pledgee is said to have a 'special property', meaning 'possession' as distinct from ownership. It is a bailment of tangible property (choses in possession), in which the pledgee obtains the legal interest of possession. At Common Law (unlike the position under civil law) it is not possible to grant a pledge over pure intangible property (chose in action) such as a debt, as that form of property does not have a physical manifestation and hence is incapable of possession. Where choses in action are embodied in documentation (a documentary intangible), as in the case of bills of exchange, a pledge may be taken.

More common, however, as security over personal property are the nonpossessory security interests of mortgage and charge. They can be taken over all forms of personal property and not just choses in possession.

The mortgage involves a transfer of title by the debtor who owns the property (mortgagor) to the creditor (mortgagee), on the basis that the title will be retransferred on repayment of the debt. The transfer of title may take place at law, giving rise to a legal mortgage. In theory, the transfer of legal title brings with it a transfer of possession where the property is goods, although it is common practice for the mortgagor to remain in possession. A transfer of title may alternatively take place in equity, giving rise to an equitable mortgage. Although in both cases, the interest of 'title' is transferred to the mortgagee, the mortgagor has long been recognized as having an equitable interest in that property (known as 'the equity of redemption'). A mortgagee's remedies include the remedies of sale, possession, appointment of a receiver, and foreclosure, the latter being a means whereby the mortgagee seeks court approval to extinguish the equity of redemption and take ownership of the property.

In practice in modern commercial life, it is common for companies to use the equitable charge as their preferred form of security over personal property. A charge is commonly described in terms of the borrower (chargor) appropriating property for the satisfaction of an obligation owed to the lender (chargee). It can operate as a 'fixed' security, meaning that it attaches to the property at the time of its creation as an enforceable contract. During the nineteenth century, however, courts exercising equitable jurisdiction additionally recognized the existence of a 'floating charge' in response to industrial and commercial needs (Pennington, 1960). The floating charge has been described as 'an interest not in specific assets but in

a constantly changing fund of assets' (Gullifer, 2008: 123). For as long as the charge continues to float, the chargor can deal with the assets in the ordinary course of business. Hence it is a particularly useful form of security in relation to inventory. A floating charge may crystallize, meaning that it becomes fixed and attached to specific property precluding the chargor from dealing with it. Crystallization happens on the occurrence of certain events impacting on the chargor; namely, liquidation, receivership, cessation of business, and defaults so specified in the charge agreement.

Charges can also be taken over land, as indeed can equitable mortgages. It is important, however, not to confuse a charge in the sense described above with the formal 'charge by way of legal mortgage', which has been used in England since the mid-1920s as a form of security over land. It is now the only statutory form that can be used over registered land (being land regulated by registration legislation, currently the Land Registration Act 2002). This charge by way of legal mortgage does not involve any transfer of legal title, thereby differentiating it from the traditional Common Law mortgage. The Common Law mortgage, discussed above in relation to personal property, had emerged in relation to land by the fifteenth century and survived until the mid-1920s (Harpum et al., 2012), itself differing from earlier forms of security over land which involved the mortgagee possessing the land under a lease and obtaining ownership on default under the terms of the lease (Holdsworth, 1923).

The creditor holding security under the charge by way of legal mortgage has statutory powers equivalent to that of a mortgagee at common law (Gray and Gray, 2009). Remedies capable of exercise therefore include sale, foreclosure, possession, and appointment of a receiver. Statutory charges over land, described as mortgages, can be found in other Common Law jurisdictions which since the nineteenth century adopted a conveyancing system, known colloquially as 'Torrens title'. It takes its name from Sir Robert Torrens who is credited with the introduction of initial legislation in South Australia in 1858, although it is said to be based on 'Hanseatic systems of mercantile registration' (Gray and Gray, 2009: 187). It has been adopted in other countries, including New Zealand, parts of Canada, parts of South East Asia, Africa, and the Carribean (Butt, 2010) and is described as 'the inspirational force' behind the English land registration schemes (Gray and Gray, 2009: 188).

French and German Civil Code Frameworks

The most influential civil law codes in the world are generally acknowledged to be the French (1804) and the German (1896) codes. They have each provided the basis for codification in many other countries.

The French Code Civil deals extensively with security in Title II *des sûretés réelles* (of real securities, Articles 2323–2373). Common forms of security over immovables governed by the Code Civil are the *hypothèque* (mortgage, Article 2393), the *privilège du prêteur de deniers* (lender's privilege, Article 2374, 2379) and the *gage immobilier* (Antichresis, Article 2387) (Cabrillac and Mouley, 1990). The *hypothèque* is a non-possessory security interest providing the creditor with a preferred right in the property regardless of who is owner at the time of execution. In order to be enforceable against third parties, it must be registered in the local land registry. Successive *hypothèques* rank according to their date of registration. In certain circumstances, a *hypothèque* may subsequently secure debts other than the one through which it was originally created (rechargeable *hypothèque*, Article 2422).

The *privilège du prêteur de deniers* is a nonpossessory security interest held by the lender who provided the funds to acquire the immovable. The lender obtains a preferential right over the potential proceeds from the property, subject to certain conditions and registration within 2 months. This security is less expensive and requires fewer formalities than the *hypothèque*. It is often the preferred form of security over immovables (Boughida et al., 2011).

In contrast to both *hypothèque* and *privilege*, the *gage immobilier* provides the creditor with possession of the property and the rights to the profits and revenue. However, this type of security is not used in practice (Boughida et al., 2011).

The Code Civil security over tangible movables (actual or future) such as goods, animals, furniture, and materials is the gage (pledge, *gage de meubles corporels*, Article 2333). A *gage* is a security interest in the movable that is effective against third parties if the movable is delivered to the creditor (*gage avec dépossession*) or through registration of the security in a special register held at the applicable court office (*gage sans dépossession*, Article 2338). In the case of default, the creditor may sell the property subject to the *gage* by court order or it may be agreed that the creditor becomes owner of the property. If the value of the property exceeds that of the debt, the difference is payable to the debtor or other secured creditors. The taking of security over inventory is regulated by the French Commercial Code (Articles L. 527-1 to L. 527-11, Code de commerce).

Security over intangible property such as shares, receivables, bank accounts, and debts can be created by the Code Civil *nantissement* (security, pledge, *nantissement de meubles incorporels*, Article 2355). Like the *gage*, the *nantissement* is the allocation of a set of actual or future assets as security for a loan. In the case of default, the assets subject to the *nantissement* are assigned to the creditor by court order or prior agreement. Sums in excess of the secured debt are paid to the debtor. Receivables are more commonly assigned by way of security according to the provisions of the French *Code monétaire et financier* (Articles L. 313-23). Here, ownership of the receivable is assigned to the credit institution upfront (Hubert, 2010).

The German Civil Code (BGB) provides specific regulations for the taking of security over land and buildings through the *Hypothek* (*Hypothec*, BGB §1113), the *Grundschuld* (land charge, BGB §1191) and the *Rentenschuld* (annuity land charge, BGB §1199); and over movables and rights through the *Pfand* (pledge, BGB §1204, 1273). While the provisions of the code satisfy commercial requirements in relation to the taking of security over land and buildings, the absence of nonpossessory security over movables and limitations with respect to security over claims to money and other rights, has led to the development of contractual forms of security outside the civil code (*Sicherungstreuhand* – security trust), where ownership is transferred to the creditor by agreement (Bülow, 2012).

In German property law, *Hypothek*, *Grundschuld*, *Rentenschuld*, and *Pfand* are classified as limited rights of ownership (Wolff and Raiser, 1957). The power that these rights provide is that of execution. The holder, on nonpayment of a claim, can seek execution against the property to which the security extends and be compensated from the proceeds.

Security interests over land are created by entry in the land registry (*Grundbuch*) and cannot exist without registration (Bülow, 2012). The *Hypothek* is accessory and requires an associated credit contract, while the *Grundschuld* and *Rentenschuld* are nonaccessory (abstract) and can exist without a claim or loan. This means that a land owner can raise funds or meet obligations by selling a *Grundschuld* over the desired amount without being a party to a loan contract (Wolff and Raiser, 1957). More common, however, is the creation of a *Grundschuld* alongside a credit contract (*Sicherungsgrundschuld* – security land charge). The differences between *Hypothek* and *Grundschuld* from an economic viewpoint are small, but the independence of the *Grundschuld* from the underlying claim can provide advantages to the creditor. On repayment of the loan, the *Grundschuld* remains in the hands of the creditor and the transfer to the debtor can be tied to other conditions (Bülow, 2012). The *Grundschuld* has become the most common security over real estate in Germany. The *Rentenschuld* is similar to the *Grundschuld* but provides for an annuity payment. This form of security has not been successful in practice (Bülow, 2012).

The priority of security rights over land is determined by the date and time of registration. The first highest ranking creditor is fully compensated from the execution proceeds (if these are sufficient), while the next secured creditor is compensated from what remains. The same process applies to subsequent creditors. Any residual sum falls to the debtor (Bülow, 2012).

The German civil law *Pfand* in relation to movables requires the delivery of the property to the creditor. An important application is refinancing (Lombard) loans between the German central bank and commercial banks as part of the European Central Bank system, which can be secured by bank bills and other debt securities. Another example is bank loans that are secured by shares on deposit with a bank (Bülow, 2012).

The taking of security over movables, where possession of property must stay with the debtor is implemented through contractual agreement (*Sicherungstreuhand*). It is effected by *Sicherungsuebertragung* (security transfer) which is the transfer of ownership and indirect possession (utilizing BGB §930 – constructive delivery) to the creditor for security purposes. The direct possession stays with the debtor. An important application relates to goods stored in a warehouse. In this case the security interest extends to future goods that replace those exiting the warehouse (Bülow, 2012).

Security over rights such as patents, trademarks, negotiable instruments, and claims to money are typically implemented by contractual agreement, the *Sicherungsabtretung* (security assignment), rather than the civil code *Pfand*. Here the right is assigned to the creditor for security purposes. In the case of claims to money, this avoids the requirements to make the security transaction known to the debtor (BGB §1280) and also simplifies the realization of the security (Bülow, 2012).

Efforts are underway to further harmonize security interests within the European Union. The directive of the European Parliament and the Council on credit arrangements related to residential property (also referred to as the *Euro-hypothec*) seeks to harmonize the underlying loan contracts. Principles for the taking of security over movable assets have been outlined in Book IX of the Draft Common Reference Framework for Principles, Definitions, and Model Rules of European Private Law (Von Bar et al., 2009) (see Functional Approach below).

The Functional Approach

A functional approach to security law looks beyond the actual form that a particular transaction takes, such as for example a pledge or a mortgage. Rather, it focuses on its function, considering whether the transaction gives rise to an interest in property which has the effect of securing payment or performance.

This approach to security has its origins in the US Uniform Commercial Code. Although law in the United States was initially based on English Common Law (McPherson, 2007), English and American security law diverged considerably during the nineteenth and twentieth centuries. Concern over the potential for fraud on creditors precluded judicial recognition of the floating charge (see English Common Law above).

The absence of such a flexible and economically important device resulted, at least in part, in increasing the technicality of various forms of security. A new approach was adopted from the 1950s under Article 9 of the Uniform Commercial Code (Gilmore, 1965), which has subsequently been revised on a number of occasions.

Article 9's influence has since spread to both Common Law and civil law jurisdictions, leading to significant changes in security law regimes. Prominent examples of Common Law jurisdictions are the Canadian Common Law provinces, New Zealand, and Australia, each of whom have enacted personal property securities legislation, from Ontario in 1967 to New Zealand in 1999 and Australia in 2009. The functional approach of Article 9 is reflected at an international level in the 'Convention on International Interests in Mobile Equipment' (known as the Capetown Convention), which offers a special security regime for aircraft, railway rolling stock, and space assets. It can also be found in the Legislative Guide on Secured Transactions, published by United Nations Commission on International Trade Law (UNCITRAL) in 2010 (McCormack, 2011). Building on earlier work carried out by bodies such as the European Development and Reconstruction Bank and the Asian Development Bank, the Legislative Guide provides a general model for countries wishing either to modernize their existing security law or to introduce 'efficient and effective… laws' (UNCITRAL, 2010: 1, 3–4). A similar trend is evident in Book IX of the Draft Common Reference Framework (see Section on French and German law above).

A functional approach typically extends the concept of a security interest beyond security interests granted by a borrower and encompasses other interests which are functionally equivalent, most notably the reservation of title arrangements, whether arising under conditional sale

agreements, hire purchase, or security (or finance) leases. It also may explicitly include some other types of arrangements which do not actually secure payment or performance of an obligation. Outright transfers of particular types of debts may, for example, be included. Also included in some jurisdictions are certain operating leases, generally those for more than a term of 1 year where the lessor is regularly engaged in the business of leasing goods. Under these arrangements, the lessee is commonly regarded as having sufficient rights in the property for a security interest to attach to the goods and not merely the possessory interest in those goods. The lessor thus finds itself in competition with other parties having security over the lessee's assets.

Security interests created under this type of legislation are interpreted as fixed in nature, leaving no room for the operation of a floating security (see English Common Law above). In the absence of agreement to the contrary between the secured party and the debtor, a security interest may continue in the secured property despite the debtor dealing with it by, for example, selling or leasing it to a third party. This has necessitated the express inclusion of rules whereby those third parties may be able to take the property free of security interests. The statutory regimes also provide a comprehensive framework for resolving competing priority claims, generally based initially on the secured party having perfected its security interest. For policy reasons, however, certain types of secured parties may be preferred, such as vendors and lenders providing credit for the purchase of an asset where those secured parties' interests are characterized as purchase money security interests and where they have complied with relevant procedural requirements for registration.

A striking feature of these statutory regimes is the concept of notice filing or registration of claims to a security interest, as distinct from the more traditional concept of registration of the actual security interest. Also of note is the provision of specific statutory remedies for enforcement.

The Economic Importance of Security

Security rights are critical in any monetary economy, because the creation of money relies on the ability to encumber property by way of security for loans (Decker, 2013; Heinsohn and Steiger, 2013). When central bank money is created, commercial banks enter into loan contracts with the central note-issuing bank, which must be secured by eligible central bank collateral (Alternative modes of money creation are repurchase agreements, which resemble secured loans, and outright purchases).

The critical role of security in this process is particularly visible during a liquidity crisis. When acting as a lender of last resort, a central bank must provide funds to anyone who can furnish sound loan security (Bagehot, 1873; Heinsohn and Steiger, 2013). In fact, all principal property classes of an economy must be able to be monetized in a crisis (Decker, 2010, 2012). This became apparent, for instance, during the 2008 global financial crisis, where central banks around the world had to widen the types of assets eligible for central bank loans. Another insightful example is the German Hyperinflation of 1923, where the German monetary system was completely disrupted as the central bank monetized an ever increasing amount of government debt. The situation was eventually resolved through the issue of a new currency backed by a priority land charge that was imposed by the government on all land used for agricultural, forestry, or horticultural purposes (at 4 or 5% of the assessed land value) together with a matching first ranking debenture on all industrial assets (Wolff and Raiser, 1957; Decker, 2012). With the property foundation thus reestablished, the currency was stabilized with surprising rapidity.

If central banks are reliant on security, so are commercial banks. The latter create funds in the form of bank deposits through loans to nonbanking institutions, the majority of which are secured. In their essence, banks are lenders on security and not providers of unsecured funds such as venture capital, as any entrepreneur can attest. Banks are therefore best understood as creators of funds rather than intermediaries (Hawtrey, 1923; Schumpeter, 1954). Banks 'transmute' (Crowther, 1940) property assets into money. Since the invention of property rights and money, loan security has played an integral part in this process.

When a note-issuing bank creates money for a debtor when granting a loan, the bank has to back the issued notes with its capital. At the same time the debtor must provide loan security as part of the loan. Both parties place a burden on their property in this process. While still in physical possession, both parties can no longer freely dispose of their assets. It has been argued that the economic implication is that both parties have lost 'ownership premium'. The latter is a yield that is attached to property that is unencumbered and free and explains why interest is charged as part of a loan (Heinsohn and Steiger, 2013).

It has been argued that ownership premium and loan security also play an important role during an economic crisis. As property owners try to protect themselves from asset losses, the ownership premium rises, reducing the amount of property that is made available for the purposes of money creation. As the prices of assets are deflated in this process, banks are forced to 'write down' their assets reducing their capital and their ability to make loans. At the same time near-insolvent borrowers can no longer provide security to renew their loans. Central bank action is hampered because it can neither directly recapitalize banks nor provide to businesses the missing loan security required for fresh loans (Heinsohn and Decker, 2010).

Loan security is also considered to be a critical factor in economic development. The limited access to formal security rights for large parts of the population in developing countries creates the issue of 'dead capital' (De Soto, 2000). While large amounts of assets exist, these have been created in the extra-legal sector and 'cannot readily be turned into capital' and used as security for loans (De Soto, 2000: 5). This is now regarded as one of the key reasons for lack of development and programs have been set up to facilitate the establishment of improved security law around the world (see, for example, United Nations, 2010; Alvarez de la Campa et al., 2012).

Segregation, Demographic Effects of

Michael J White, Population Studies and Training Center, Brown University, Providence, RI, USA

Abstract

An abiding concern in the study of segregation is that the residential clustering would itself influence social outcomes, either by changing behavior or by changing the structure of opportunities. The premise is that residential clustering carries behavioral consequences beyond those of ethnicity, socioeconomic status, or life cycle stage. A number of models advance a causal connection between this geographic clustering of traits and social behaviors that result. Contemporary research approaches to the issue generally involve multivariate, multilevel models. Increasingly, the availability of such data allows for a more sophisticated examination of this issue than heretofore. Multivariate studies have examined the effects of segregation and neighborhood composition on a wide array of outcomes, from health to schooling to child development. Investigators continue to deal with methodological challenges associated with such analyses, but accumulated research reveals the value of adding residential context to models of social and behavioral outcomes.

Segregation is the differential distribution of social groups. Most commonly, the use of the term refers to residential segregation, the differential distribution of social groups across geography. Residential segregation has served as a key indicator of social differentiation for decades. (*See* Residential Segregation in the United States in this volume for a general review.) Segregation is usually measured by one or more summary indices, designed to reflect the differential distribution of persons or other social units across neighborhoods, occupations, or other categories (White, 1986). Nowadays, segregation is often seen as a multidimensional phenomenon tapped by a variety of indices (Massey et al., 1996; Wilkes and Iceland, 2004). While the bulk of work has centered on residential segregation among ethnic groups, virtually any trait could be considered, and research has examined segregation by income, education, occupation, nativity, age, and other demographic traits. A line of research also strives to examine the relative contribution of group income differentials in determining (confounding) observed racial and ethnic segregation (Iceland and Wilkes, 2006; Fischer, 2003). Racial segregation across schools and occupations remains an important indicator of social distance more generally.

Beyond the measurement of segregation itself, there has always been interest in the consequences of residential clustering. Theory can be invoked to suggest positive as well as negative consequences (Cutler and Glaeser, 1997; Bell et al., 2006). This ranges from the ways in which residential concentration might generate employment networks or social support institutions, to the consequences of residential isolation for educational attainment or health outcomes. From the point of view of policy, the determinants and consequences of segregation are of particular interest. There has been heightened attention to the aftermath of living in or being raised in a segregated or disadvantaged neighborhood.

Considerable empirical work has now accumulated to investigate the effects of residential segregation and related phenomena. The underlying concept is that residential clustering carries behavioral consequences beyond those of ethnicity, socioeconomic status, or lifestyle. Such notions have been present in demography and allied social sciences for some time. Indeed, the residential neighborhood may be seen as one of the several very important contextual settings helping to shape outcomes for the individual person (Brooks-Gunn et al., 1993; Massey, 2014). If anything, the concerns about the effects of local environment – from household, through immediate neighborhood, to residential community and school district – have grown with time and additional research on social inequality. At the same time, however, a number of observers have raised doubts about the depth of our understanding of spatial (segregation) mechanisms and/or the ability to alter those environments, especially for disadvantaged individuals (Burdick-Will et al., 2011; DeLuca and Dayton, 2009; Sampson, 2008).

It is important to distinguish the influence of composition from that of behavioral causation. For instance, the receipt of public assistance varies appreciably across urban neighborhoods. The degree to which this behavior can be linked causally to the concentration of social groups in neighborhoods (and the sociological patterns that arise through clustering) needs to be weighed against an explanation based just on composition. The key question turns on whether geographic clustering itself influences behavior, beyond that attributable to other background traits, such as age and education.

Since this article is dedicated to the consequences of segregation, the causal direction of interest runs *from* the neighborhood or community aggregate; one should also note that mechanisms can run from individual or household behavior *to* the neighborhood, thereby generating segregation through process of selection (or restriction), often via local geographic mobility.

Many demographic traits are segregated in urban neighborhoods, and there is a consistency to the ranking. Although empirical results on these matters derive preponderantly from North America, results are accumulating for other high-income societies (Johnston et al., 2007; Musterd, 2005). Racial and ethnic groups remain very highly segregated in most urban areas. Several decades of study, from straightforward segregation measures through factorial ecology and the like, have verified the sorting of urban space along the lines of socioeconomic status. Life cycle stage is also differentiated.

Segregation indices for sex and age are generally modest, although segregation for household size and type is more discernible. Of course, certain special concentrations of population, such as group quarters for military populations, students, and those under correctional supervision, are highly segregated and are often excluded from consideration by analysts.

Contemporary statistical estimates of neighborhood effects rely on hierarchical and multilevel models. While strategies differ, the general approach is to develop a multivariate model, in which the behavioral and demographic outcome (employment, childbearing) is taken to be first a function of fixed personal traits and a set of family and household background factors. Neighborhood and community characteristics are introduced to the model simultaneously or sequentially. With the availability of multilevel statistical techniques and associated software, it is possible to derive more sophisticated (and econometrically appropriate) estimates of neighborhood or community effects. Some of the same conceptual and methodological apparatus can be applied to patterns or demographic unevenness found in other contextual social settings, such as the workplace or schools.

Mechanisms through Which Segregation May Influence Demographic Outcomes

Beyond the simple mechanism of demographic composition itself, segregation and differential concentration might influence outcomes in several ways. The outcomes can be placed within three groupings: (1) contagion or socialization effects; (2) resource allocation; and (3) institutional structures. (Various authors differ in identifying and labeling mechanisms. Leventhal and Brooks-Gunn (2000) make reference to three types of mechanisms: institutional resources, relationships, and norms/collective efficacy.) Contagion and socialization models, also closely linked to epidemic effects and diffusion models, have a long history in social science thinking. Simply stated, individuals alter their behavior on the basis of their interpretation of those around them (Jencks and Mayer, 1990; Sampson et al., 2002). The influence of peers on child behavior is one such critical mechanism. The general reasoning (see, e.g., Wilson, 1987) is that low-income or disadvantaged neighborhoods offer fewer mainstream role models (dual parent families, stable adult workers, school completion); by contrast one is exposed to different conditions and social behaviors, so persons growing up in such areas do not acquire mainstream norms. Massey and Denton argued that the intersection of poverty and segregation creates an environment where such conditions abound (Massey and Denton, 1993). Much discussion surrounding the impact of growing up in a disadvantaged inner city neighborhood or attending an inferior school draws on this line of thinking, and the mechanism attracts increasing concern in the field of health (Diez-Roux, 2001; Diez-Roux and Mair, 2010; Kawachi and Subramanian, 2007; Robert, 1999).

A second line of thinking involves resource allocation. Residents of affluent neighborhoods (or workers in advantaged workplaces) can provide superior public goods, either through direct community provision or through the political process. More than that, these public goods are likely to confer advantages that go beyond the immediate advantages of household and family. Conversely competition over scarce resources may influence behaviors and outcomes in disadvantaged neighborhoods. And related thinking along these lines concentrates on the impact of relative deprivation, rather than absolute conditions. Other externalities of clustering include relative advantage or deprivation in local sanitation (exposure to pathogens and toxins), public safety, and the like. Housing experiments, such as those relocating low-income individuals to middle-income communities, are often premised on such mechanisms. As is clear from discussion over how to interpret such interventions, disentangling causal mechanisms is not an easy task (DeLuca and Dayton, 2009; Sampson, 2008).

The third line of thinking involves the growth and maintenance of local institutions, whether formal or informal (Duncan, 1994). The literature identifies both positive and negative consequences of segregation. In the realm of economic outcomes, the notion of the ethnic enclave suggests that concentration, building on ethnic networks, may provide benefits. Here there would seem to be a crossover to the discussion of social capital and influences it conveys. Occupational and residential segregation among co-ethnics may generate employment opportunities unavailable in a more integrated economy. A long-standing argument is that racial residential segregation enables integration by social class. In an urban neighborhood, local institutions, such as a church or neighborhood association, might foster social ties across class boundaries, although even historical accounts of ghetto life do not always portray a comfortable coexistence of disparate groups. These evolving structures can serve as social actors and then influence behavioral outcomes for other members of the community. Challenges for empirical work along these lines involve adequately identifying institutional structures and then teasing out the influences of institutions, net of individual, family, and other community traits.

Methodological Issues

The study of the effects of segregation raises several methodological issues. A fundamental issue is one of definition. A 'neighborhood' or local 'community' might have several competing geographic boundaries. Tracts, wards, block groups, and other urban statistical subdivisions become *de facto* neighborhoods (White, 1987). This has two consequences. First, such units serve as the basic geography for calculations of segregation measures. Second, these small statistical areas are the units that serve as the proxy for social conditions in multilevel models.

In recent years there has been a tremendous evolution in spatial thinking and modeling in the social sciences, along with accompanying methodological development to implement analysis suitable to that thinking (Logan, 2012). For decades, analysts concerned with neighborhood or other similar contexts were often constrained to ecological approaches, i.e., invoking models which relate aggregate values of demographic characteristics to one another. While some might argue for the focus on the neighborhood only, multilevel analysis can analyze outcomes as the result of both individual and

contextual (neighborhood, school) characteristics with more attention to proper statistical specification. The composition of the neighborhood or city, even the level of segregation characterizing the metropolitan region, could be one of these aggregate characteristics. Data are increasingly available in ways that link individual to context, but are promulgated or stored in a way so as to maintain confidentiality of the information for the respondents. Despite the considerable advances in data and statistical technology, challenges remain in model specification and even in correctly constructing contextual variables with respect to time and space.

Evolution of Empirical Investigation

From the earliest investigations of residential segregation, there has been interest – implicit or explicit – in its effects. A large social science literature grew rapidly around the measurement and analysis of racial and ethnic residential segregation. As interests expanded and as more small-area data became available, analyses of residential segregation spread to other demographic and social characteristics and to geographic settings beyond North America. Soon, interest arose in empirical testing of mechanisms linked to residential segregation, both as cause and consequence. The advent of superior data structures and estimation techniques quickly facilitated doing so. At the same time a companion literature has arisen discussing issues of measurement, inference, and other challenges to understanding contextual or neighborhood effects (DeLuca and Dayton, 2009; Logan, 2012; Sampson et al., 2002).

Additional work on the measurement of spatial segregation, per se, has also been underway. Considerable research accumulated on the dimensions of residential segregation, and since then investigators have turned to further consideration of the meaning of alternative measures and, of particular note, to more explicit concern for geographic scale of measurement (Reardon et al., 2008), to space itself, and to multiethnic patterns.

The empirically based literature on the effects of residential segregation is now voluminous. Much literature has grown up around a focus on the effects of concentrated disadvantage, such as the consequences of growing up in a poor neighborhood or attending a 'bad' school. After expressing reservations about the quality and consistency of data, a 1990 review of empirical studies of the effects of socioeconomic status and racial mix, for both neighborhoods and schools, concluded that there was no general pattern of effects across a wide range of outcomes (Jencks and Mayer, 1990). A more recent and comprehensive review focused on children and adolescents (Leventhal and Brooks-Gunn, 2000) identifies neighborhood effects for several education-related outcomes, for behavioral and emotional well-being, and for sexual behavior. Through this literature, the range of potential mechanisms and impacts across demographic groups and social characteristics is quite large. Qualitative approaches in neighborhood research, for instance, with regard to parenting strategies, might help uncover mechanisms (Jarrett, 1997; Leventhal and Brooks-Gunn, 2000). Effects of residential segregation, i.e., neighborhood composition, or equivalent have been found in many studies, but at the same time, the scale of these effects must be interpreted against the magnitude of other influences, particularly those of the immediate family. Given the argument for making investments at an early age in disadvantaged children (Heckman, 2006), there is a companion case for both understanding pathways through which segregation might influence outcomes and conducting the empirical work to measure their impact and for whom they operate.

One long-standing line of work looks at the influence of segregation itself. Empirical analyses often introduce a residential segregation index to a regression model of a behavioral outcome. The behavioral mechanism underlying the inclusion of such a covariate is not always clear, but higher levels of residential segregation may tap into underlying housing market constraints, a more hostile climate of local race relations, or differential access to public sector resources. Predictive power of such segregation indices is not always strong, but on balance they tend to show that individuals (usually minority group members) living in more segregated urban areas experience detrimental outcomes, such as inferior health outcomes (LaVeist, 1989; Subramanian et al., 2005), differential schooling outcomes (Card and Rothstein, 2007), or less mobility out of poverty (South and Crowder, 1997).

Recent developments in methods and data have pushed forward work on residential segregation, and companion analyses of neighborhood effects. We have clearer evidence on the ways in which residential segregation impacts a range of societal outcomes. While statistical findings are not always simple, they do reinforce the view, held by social scientists for decades, that neighborhood and context matter.

Abstract

Research on residential segregation has been a topic of social science investigation since the first studies were done by sociologists in the Chicago School during the 1920s. For many years, scholars engaged in a spirited debate about how best to measure geographic segregation but a period of methodological peace was created when Duncan and Duncan in 1955 concluded that the index of dissimilarity was the best measure. The methodological debate was renewed in the 1970s but settled once again during the 1980s after Massey and Denton linked the various indices to one of five separate dimensions of segregation. Indices for each of these dimensions are defined and discussed here and current thinking on segregation and its measurement is summarized.

Residential segregation has long been a topic of interest to social scientists, dating back to the early days of the Chicago School of Sociology. In their analyses of urban spatial patterns, for example, Burgess (1925) noted the tendency of racial and ethnic groups to separate themselves into distinct residential enclaves and Park (1925) developed a theory of ecological succession to account for the formation of these enclaves. The first systematic study of segregation was published by Burgess in 1928 and since then residential segregation has maintained a constant presence in the social science literature (see Massey (1985, 2014) and Charles (2003) for reviews). For many years, social scientists searched for the ideal index of segregation and over the years many options were proposed and debated with no clear resolution.

The First Methodological Peace

In 1955, however, Duncan and Duncan undertook a systematic review of the candidate indices and concluded that, overall, the index of dissimilarity was the best measure. This index measures segregation as the degree of departure from an even residential distribution of two social groups in urban space. An even distribution occurs when each neighborhood replicates the percentage of group members in the urban area as a whole. If blacks constitute 10% of an urban area and whites 90%, for example, then in an even distribution each neighborhood would be 10% black and 90% white and the dissimilarity index would be zero. The index may be interpreted as the relative share of group members (e.g., blacks and whites) who would have to exchange neighborhoods to achieve an even residential distribution and equals 100 when two groups share no neighborhood in common.

The Duncans' analysis ushered in two decades of methodological peace in which the index of dissimilarity was routinely applied to measure ethnic and racial segregation in diverse urban areas throughout the world but especially the United States, yielding some of the field's classic studies of racial and ethnic segregation, such as Duncan and Duncan's *The Negro Population of Chicago* (1957), Liberson's *Ethnic Patterns in American Cities* (1963), Taeuber and Taeuber's *Negroes in Cities* (1965), and Grebler et al.'s *The Mexican American People* (1970).

Index Wars and the Second Methodological Peace

The period of consensus ended in 1976, however, when Cortese, Falk, and Cohen published an article in the *American Sociological Review*, the field's over-reliance on the dissimilarity index, arguing among other things that the standard of evenness was unrealistic and suggesting that a random distribution in urban space would be a better standard of comparison.

Although practitioners such as Taueber and Taueber (1976) were unimpressed with the critique, it did set off a decade of renewed debate on the best way to measure residential segregation and in the wake of their article a variety of new measures were proposed and older indices were revived (James and Taueber, 1985). One critique of the dissimilarity index was that it was aspatial: it simply measured departures from an abstract ideal of evenness but took no account of where neighborhoods were situated geographically in the urban landscape. Several new spatially sensitive measures were introduced and some scholars proposed adjusting existing indices to take account of their spatial location (Jakubs, 1981; Morgan, 1982, 1983).

After a flurry of methodological activity, the second period of debate came to an end when Massey and Denton (1988) undertook a factor analysis of all prevailing segregation measures and identified five distinct underlying dimensions of segregation and recommended an index for each one. Massey and Denton's analysis was based on 1980 census data used to compute indices of segregation for Hispanics, African Americans, and Asians in 60 metropolitan areas, but it was later replicated by Massey et al. (1996), who reached the same conclusions using 1990 census data for these groups in all metropolitan areas. The first dimension identified by Massey and Denton (1988) was unevenness, the degree to which two groups were unevenly distributed across spatial units, and they confirmed Duncan and Duncan's selection of the index of dissimilarity as the best overall indicator for this dimension of segregation. The other four dimensions were isolation, clustering, concentration, and centralization.

Isolation is the degree to which a social group lives in neighborhoods dominated by members of the same group and to measure it Massey and Denton recommended

Lieberson's (1981) P* isolation index, which indicates the percentage of own-group members in the neighborhood of the average member of that group. The black isolation index, for example, is the percentage of blacks in the neighborhood of the average African American and it ranges from the percentage of blacks in the urban area as a whole to 100. Clustering is the degree to which neighborhoods inhabited by a group are packed together in space and is best measured by White's (1983) spatial proximity index (SP) which captures the differential clustering of two groups in residential space. For blacks and whites, the index would equal zero if black and white neighborhoods were spread around an urban area like squares on a checkerboard and 100 when all blacks are clustered together in a set of contiguous black neighborhoods and all whites are clustered together in a set of contiguous white neighborhoods.

Concentration refers to the relative amount of physical space occupied by a social group within an urban area. To measure this dimension, Massey and Denton built on earlier work by Duncan et al. (1961) to define a relative concentration index (RCO). When computed for blacks and whites, the index takes a value of zero when two groups occupy the same amount of space and 100 when blacks occupy the smallest amount of physical space possible compared with whites. Centralization is the degree to which members of a social group reside near the center of any metropolitan area and Massey and Denton (1988) again drew upon the work of Duncan et al. (1961) to define an absolute centralization index (ACE) that for blacks and whites gives the proportion of blacks who would have to change neighborhoods to achieve an even residential distribution around the geographic center of the metropolitan area.

In a follow-up article, Massey and Denton (1989) drew upon 1980 census data to measure black segregation in 60 large metropolitan areas on all five dimensions and found that as of 1980 African Americans in 16 areas were highly segregated (index value >=60 on a 0–100 scale) on at least four of the five dimensions, a condition they labeled hypersegregation. In the years since the Massey–Denton work was published, social scientists have regularly computed indices for the five dimensions of segregation they identified. Analyzing data for all metropolitan areas in 1990, Denton (1994) expanded the list of black hypersegregated areas to 29, the same number found by Wilkes and Iceland (2004) in their analysis of data from the 2000 census. Working at the US Census Bureau, Iceland et al. (2002) ultimately published a battery of indices measuring segregation on all five dimensions for blacks, Hispanics, Asians, and American Indians using data from the 1980, 1990, and 2000 censuses. Descriptions, formulae, and instructions for computing the various indices are available online at https://www.census.gov/hhes/www/housing/housing_patterns/pdf/app_b.pdf.

Current Thinking on the Measurement of Segregation

The multidimensional nature has come to be widely accepted although the dissimilarity index of unevenness and P* index if usikatuib are generally computed more often than indices of the other three dimensions (see Rugh and Massey, 2013). Although the index of dissimilarity continues to be the workhorse of segregation research, another measure of evenness has come into use to make up for the limitations of the dissimilarity index. Two drawbacks of the index of dissimilarity are that it can only be computed for two groups at a time and it is not easily partitioned into components corresponding to different sources of spatial variation.

In order to measure the degree of segregation between multiple groups at the same time (say, blacks, whites, Asians, and Latinos or five income quintiles) or to decompose overall segregation into interpretable components, investigators have turned to Theil's (1972) entropy index. Reardon and Bischoff (2011) used it to assess the degree of segregation between income classes in US metropolitan areas, whereas Fischer (2003) used it to analyze the changing importance of race/ethnicity versus class in determining a group's level of segregation, and Fischer et al. (2004) employed it to decompose segregation by race, ethnicity, class, and life cycle into separate contributions by region, metropolitan area, city-suburban residence, and census tract.

When measuring segregation between two groups, the entropy index and the dissimilarity index are highly correlated, so Theil's index has generally been applied whenever investigators seek to measure segregation between multiple groups, or to decompose segregation into analytic components. In the end, however, there is no single 'correct' index of residential segregation and investigators continue to invent and try out new options. The choice of an index depends on what dimension of segregation and the kind of analysis one seeks to conduct. The fullest picture of a group's residential segregation is probably achieved by taking a multidimensional approach, though in any given analysis investigators may wish to focus on one particular dimension of interest.

Abstract

The problem of selection bias is pervasive in the social and behavioral sciences. This article defines the problem and provides examples of where it arises. Since the 1980s, the Heckman two-step method has been the most popular method of correcting for selection bias. It is explained and the criticisms made of it are discussed. In recent years, much attention has focused on selection bias in the nonexperimental evaluation of programs. The issues in this area are briefly outlined; selection bias proves to be only one of several possible sources of bias in these circumstances. The article ends with some practical guidelines for using selection bias correction estimators in empirical research.

In almost all areas of scientific inquiry, researchers often want to infer, on the basis of sample data, the characteristics of a relationship that holds in the relevant population. Frequently, this is the relationship between a dependent variable and one or more explanatory variables. In some cases, however, although one may have complete information on the explanatory variables, information on the dependent variable is lacking for some observations or 'units.' Furthermore, whether or not this information is present may not be conditionally independent (given the model) of the value taken by the dependent variable itself. This is a case of selection bias.

Selection Bias

The following illustrates the basic problem. Suppose one hypothesizes the following relationship, in the population, between a dependent variable, Y^*, and a set of $j = 1,\ldots, J$ explanatory variables, X:

$$y_i^* = x_i'\beta + \varepsilon_i \qquad [1]$$

Here the unit-specific values of Y^* are denoted as y_i^* (where i denotes the ith observation) and each unit's values of the X variables are contained in the vector x_i. ε is a random error, and the parameter vector, β, is to be estimated. Specific assumptions about the distribution of ε will determine the choice of estimation technique.

If Y^* is considered as a latent variable, a variety of different statistical models can be generated from eqn [1] depending on the manner in which Y^* is actually observed (though still, at this point, assuming that Y^* is observed, in some fashion, for all units). To do this, write a second equation that defines the relationship between the observed variable, Y, and the latent variable, Y^*. For example, where Y^* is completely observed.

$$y_i = y_i^* \qquad [2a]$$

But one might also have

$$\begin{aligned} y_i &= 1 \quad \text{if } y_i^* > 0 \\ y_i &= 0 \quad \text{otherwise} \end{aligned} \qquad [2b]$$

In the case of eqn [2b], Y is the binary observed realization of the underlying latent variable, Y^*. More complex relationships between Y^* and Y are also possible.

To capture the idea of selection bias, suppose that there is another latent variable Z^* such that whether or not we observe a value for Y depends on the value of Z^*, which is given by

$$z_i^* = w_i'\alpha + \nu_i \qquad [3]$$

Here w is a vector of explanatory variables with coefficients α, and ν is a random error term. The observed variable Z is defined as

$$\begin{aligned} z_i &= 1 \quad \text{if } z_i^* i > 0 \\ z_i &= 0 \quad \text{otherwise} \end{aligned} \qquad [4]$$

Finally, define the observation equation for Y as depending on Z^* as follows:

$$\begin{aligned} y_i &= y_i \qquad\qquad \text{if } z_i = 1 \\ y_i &\ \text{unobserved} \quad \text{if } z_i = 0 \end{aligned} \qquad [5]$$

Equations [1], [2a], [2b], and [5], together with eqns [3] and [4], link the latent variable, Y^*, to its observed counterpart, Y, when observation of the latter depends on the value of another variable, Z^*. Selection bias occurs when there is a nonzero covariance between the error terms ε and ν. More complex selection bias models can be generated by having, for instance, more than one Z^* variable. The censored regression (or Tobit) model is a simpler case in which whether Y is observed or not depends on whether it exceeds (or, in other cases, falls below) a given threshold value.

The Problem

Selection bias is a problem because if one tries to estimate β using normal statistical methods, the resulting estimates will be poor and potentially misleading. For example, if eqn [2a] specifies the relationship between Y and Y^*, discarding cases where Y is unobserved and running an ordinary least squares (OLS) regression on the remainder will give estimates that are biased and inconsistent.

Where might this kind of selection bias arise? Suppose one draws a random sample from a population and carries out a survey. Some respondents may refuse to answer some, though not all, questions. If the response to such a question played the role of dependent variable in a regression analysis, there would be a selection bias problem if the probability of having responded to the item was not independent of the response value, given the specification of the regression model (Horowitz and Manski, 1998). This may not always be so: in the simplest case, nonresponse might be random. Alternatively,

response might be independent of the response value controlling for a set of measured covariates. In this case there is selection on observables (Heckman and Robb, 1985). But often neither of these cases holds, and a nonzero residual correlation between the selection eqn [3] and the outcome eqn [1] means that there is selection on unobservables.

In studies of the criminal justice system in which the population includes all those charged with a crime, sentence severity is observed only for those found guilty. In studies of the effectiveness of university education, the outcome (say, examination results) is only observed for those who had completed that period of education. In studies of women's earnings in paid work, the earnings of women who are not in the labor force cannot be observed. To these examples could be added very many more. Selection bias is a pervasive problem. As a consequence, a variety of methods has been proposed to deal with it.

The problem of selection bias arises because of the nonzero correlation of the errors in eqns [1] and [3], and this arises commonly in the following context. Suppose there is a nonexperimental comparison of two groups, one exposed to some policy treatment, the other not. In this case, the outcome of interest, Y, could be observed for members of both groups. Let Z now be the indicator of group membership (so that, for instance, $Z = 0$ means membership of the comparison group and $Z = 1$ means membership of the treatment group). In the case where eqn [2a] holds, write the equation for Y as

$$y_i = x_i'\beta + \gamma z_i + \varepsilon_i \qquad [6]$$

and interest would focus on the estimate of γ as the gross effect on the outcome measure of being in the treatment, rather than the comparison, group. The problem of selection bias still arises to the extent that ε and ν have a nonzero correlation. The difference between this and the type of selection bias discussed initially (namely, that now Y is observed for both groups) is more apparent than real as an alternative formulation shows. For each unit Y is observed as the response to membership of either the treatment or comparison group, but not both. Let Y_1 be the outcome given treatment and Y_0 given no treatment. Then the ith individual unit's gain from treatment is simply $\Delta_i = Y_{1i} - Y_{0i}$. But Δ cannot be measured, since one cannot simultaneously observe a unit's values of Y_1 and Y_0. Instead

$$Y_i = ZY_{1i} + (1 - Z)Y_{0i} \qquad [7]$$

is observed. Equation [7] thus specifies the incomplete observation of two latent variables, Y_0 and Y_1. This setup can easily be extended to cases with more than two groups. As might be expected, this approach is commonly encountered in the evaluation literature, but one of its earliest formulations was by Roy (1951) as the problem of self-selection. More recent works treat the problem of selection as a particular case of a broader set of challenges in the identification of causal effects (Pearl, 2009; Rubin, 2005).

The Solutions

Broadly speaking, there are two ways to address problems of selection bias: *ex ante* by research design and *ex post* by statistical adjustment. The modern literature on correcting for selection bias is itself biased toward the latter, beginning with the work of Heckman in the 1970s (Heckman, 1976, 1979), whose so-called 'two-step' method is widely used and hardwired into many econometrics programs. The argument that underlies this technique is the following: Assume the setup as defined by eqns [1]–[5] and a nonzero covariance between ε and ν. Then, we can write the 'outcome equation' (i.e., the regression equation for Y, given its observability) as

$$E(y_i|z_i = 1, x_i) = x_i'\beta + E(\varepsilon_i|z_i = 1) \qquad [8]$$

Because there are only observations of Y when $z = 1$, there is an extra term for the conditional expectation of ε. Because of the nonzero covariance between ε and ν and if, as is usually assumed, $E(\varepsilon) = 0$, this conditional expectation cannot be zero. One can write

$$E(y_i|z_i = 1, x_i) = x_i'\beta + E(\varepsilon_i|\nu_i > w_i'\alpha) \qquad [9]$$

Using a standard result for the value of a truncated bivariate normal distribution, the second term on the right-hand side of this equation is given by

$$E(\varepsilon_i|\nu_i > w_i'\alpha) = \rho\sigma_\varepsilon\sigma_\nu\frac{\phi(w_i'\alpha)}{\Phi(w_i'\alpha)} \qquad [10]$$

Here the σ's are the standard deviations of the respective error terms from eqns [1] and [3]; ρ is the correlation between them; ϕ and Φ are, respectively, the density and distribution functions of the standard normal and their ratio, as it appears in eqn [10], is termed the 'inverse Mill's ratio.' Heckman's two-step method requires first running a probit regression with Z as the dependent variable, estimated using all the observations in the data. Then, for those observations for which Y is observed, the probit coefficient estimates are used to compute the value of the inverse Mill's ratio. This is then inserted as an extra variable in the OLS regression in which Y is the dependent variable to give

$$E(y_i|z_i = 1, x_i) = x_i'\beta + \theta\widehat{\lambda}_i \qquad [11]$$

where λ is the inverse Mill's ratio and the 'hat' indicates that it is estimated. Its coefficient, θ, is then itself an estimate of $\rho\sigma_\varepsilon\sigma_\nu$. This is the covariance between ε and ν (σ_ν is set to unity in the probit). This approach is extended readily to the case in which an outcome is observed for both groups ($Z = 0$ and $Z = 1$).

What are the assumptions of this approach and what are the properties of the resulting estimator when we apply this method to data from a sample of the population? First, it is assumed that all the other requirements for an OLS regression are met. Second, in the setup outlined above, the joint distribution of ε and ν should be bivariate normal (though, in general, weaker assumptions suffice, namely that ν be normally distributed; and the expectation of ε, conditional on ν, should be linear in ν (see Olsen, 1980)).

Given that the assumptions hold, the two-step estimator yields consistent estimates of the population β in eqn [1]. The standard errors are incorrect (due to heteroscedasticity and the use of an estimated value of λ), but these are corrected readily. An alternative to the two-step approach is to estimate both the selection and outcome equations simultaneously using maximum likelihood (ML). The resulting estimates are asymptotically unbiased and more efficient than those from

the two-step method (see Nelson (1984) for a comparison of OLS, the two-step method, and ML).

This two-step method is, in any case, applicable only when the relationship between Y^* and Y is as given by eqn [2a]. When this relationship is given by, for example, eqn [2b], the two-stage method is inconsistent. In these cases, ML is the most feasible option. If the outcome variable is itself binary, the joint log-likelihood of the selection and outcome equations has the same general as for a bivariate probit but one in which there are three, rather than four, possible outcomes. They are $z = 1$ and $y = 1$; $z = 1$ and $y = 0$; and $z = 0$ (in which case y is not observed).

Although the two-step method is probably the most widely used approach to correcting for selection bias, it has been subjected to much criticism. Among the main objections are the following:

1. *Sensitivity to distributional assumptions*. Practical implementation of the method renders it particularly sensitive in this respect. If the assumptions are not met, the estimator has no desirable properties (i.e., it is not even consistent).
2. *Identification and robustness*. It is common to find that the estimate of the inverse Mill's ratio is highly correlated either with the explanatory variables or with the intercept in eqn [11]. The extent to which such problems will arise depends mainly on three things. They are
   1. the specification of the selection equation;
   2. the sample correlation between the two sets of explanatory variables, X and W (call this q);
   3. the degree of sample selection in the sample (p, the proportion of cases for which $z = 1$).

For example, if X and W are identical, the two-equation system is identified only because of the nonlinearity of the probit equation. But for some ranges of p the probit function is almost linear, with the result that the estimated λ will be close to a linear function of the explanatory variables in the probit; and thus it will be highly correlated with the X variables in the outcome equation. In general, the correlation between the inverse Mill's ratio estimate and the other explanatory variables in this equation will be greater, the greater is q and the closer is p to zero or one (this issue is discussed in detail in Breen, 1996). If the selection equation does not discriminate well between the selected and unselected observations, the estimated inverse Mill's ratio will be approximately a constant, and there will therefore be a high correlation between it and the intercept of the outcome equation.

Both these objections reflect genuine difficulties in applying the model. In principle, the solution to the identification and robustness problems is simple: ensure that the probit equation discriminates well and does not rely on the nonlinearity of the probit for identification. In practice it may be rather difficult to achieve these things. On the other hand, the issue of distributional assumptions may be even less tractable, obliging recourse to semiparametric or other approaches (Manski, 1995; Lee, 1994; Cosslett, 1991).

An alternative is to try to assess the likely degree of bias that sample selection might induce in a given case. Rubin (1977) presents a Bayesian approach in which the investigator computes the likely degree of bias, conditional on a prior belief about the relationship between the parameters of the distribution of Y in the selected and nonselected samples. The mean and the variance of the latter sample might, for example, be expressed as a function of their values in the selected sample, conditioning on the values of observed covariates. It is then straightforward to express the extent of selection bias for plausible values of the parameters of this function and to place a corresponding Bayesian probability interval around any estimates. Rosenbaum (1995, 1996) suggests and illustrates other sensitivity analyses for selection bias in nonexperimental evaluations.

Program Evaluation and Selection Bias

For several years now the literature on selection bias has been dominated by discussion of how to evaluate programs (such as job training programs) when randomized assignment to treatment and control group is not possible (Imbens and Wooldridge, 2009). In a very widely cited paper, Lalonde (1986) compared the measured effectiveness of labor market programs using a randomized assignment design with their effectiveness computed using the Heckman method and showed that they led to quite different results (but see also Heckman and Hotz, 1989). While some have seen this as a fatal criticism of the method, one consequence has been the development of greater awareness of the need to ensure the suitability of different selection bias correction approaches for specific cases. Another has been a greater concern to identify other possible sources of bias in nonrandomized program evaluations.

In the statistical literature, matching methods commonly are advocated in program evaluations in the absence of randomization. They involve the direct comparison of treated and untreated units that share common, or very similar, values on a set of relevant covariates, X. The rationale for this is the assumption that, conditional on X, and assuming only selection on observables (all of which are in X), the observed outcome for nonparticipants has the same distribution as the unobserved outcome that participants would have had, had they not participated (see Heckman et al., 1997). This then allows one to estimate Δ. In passing, note that matching is also used commonly to impute missing values in item nonresponse in surveys (Little and Rubin, 1987). A central issue is how to carry out such matching. If there are K covariates, then the problem is one of matching pairs, or sets, of participants and nonparticipants in this K-dimensional space. But by a result due to Rosenbaum and Rubin (1983) (see also Rosenbaum, 1995), matching using a scalar quantity called the propensity score is equally effective. The propensity score is simply the probability of being in the treatment, rather than the comparison group, given the observed covariates. Matching on the propensity score controls bias due to all observed covariates, and even if there is selection on unobservables, the method nevertheless produces treatment and comparison groups with the same distribution of X variables. This is so under the assumption that the true propensity score is known, but Rosenbaum and Rubin (1984) show that an estimated propensity score (typically using a logit model) appears to perform at least as well.

The use of matching draws attention to the problem of the possibly different distributions of covariates (or, equally, of propensity scores) in the treatment and comparison groups. There are two important aspects: First, the support of the propensity score may be different, so some ranges of propensity score values may be present in one group and not the other. More simply, some participants may have no comparable nonparticipants. Second, the distributions of the set of common values of propensity scores (i.e., which appear in both groups) may be different (Heckman et al., 1997, 1998). Hitherto, in practice, both of these sources of bias in evaluating the program's effects commonly would have been confounded with selection bias proper. The use of propensity scores can remove the former but, if there is also selection on unobservables (i.e., selection bias proper), matching cannot be expected to solve the problem (Caliendo and Kopeinig, 2008; Imbens, 2014). Indeed, it is possible that these different forms of bias may have opposite signs, so that correcting for some but not others may make the overall bias greater. Nevertheless, the ability to draw such finer distinctions among biases is a valuable development, not least because it allows one to focus on methods for controlling selection bias, free from the contaminating effects of other biases.

Conclusion

This article has only skimmed the surface of selection bias statistics. In particular, it has looked only at models for cross-sectional data: other approaches are possible given other sorts of data. For example, given longitudinal data, with observations of Y for each unit at two (or more) points in time, one prior to the program to be evaluated and the other after it, then it may be possible to specify and test a model which assumes that unobserved causes of selection bias are unit-specific and time-invariant, and can therefore be removed by differencing (Heckman and Robb, 1985; Heckman et al., 1997, 1998). Considerations of this sort draw attention to the *ex ante* approach to dealing with selection bias that was referred to earlier. Here the emphasis falls on designing research so as to remove, or at least reduce, selection bias. Random assignment is one possibility, though not always feasible in practice. Nevertheless, quasi-experimental approaches, interrupted time series, and longitudinal designs with repeated measures on the outcome variable are among a range of possibilities that could be considered in designing one's research to minimize selection bias problems (see Rosenbaum (1999) and associated comments). Even so, there will still be many instances in which analysts use data over whose collection they have had no control and where the use of *ex post* adjustments will be unavoidable.

To conclude, much work on the selection bias problem has been undertaken since the 1980s, yet there is no widespread agreement on which statistical methods are most suitable for use in correcting for the problem. Some broad guidelines for practitioners can, however, be discerned as follows:

1. the need to ensure that methods to correct for selection bias are appropriate and that their requirements (such as distributional properties) are met;
2. the need to be aware of other, possibly confounding, sources of bias (Bareinboim and Pearl, 2012);
3. the usefulness of analyses of the sensitivity of conclusions to various possible magnitudes of selection bias, and of the sensitivity of the selection bias corrected results to the assumptions of whatever method is employed; and
4. the desirability of designing research so that selection bias problems are, as far as possible, eliminated without the need for complex and sometimes fragile *ex post* adjustment.

Self and Brain

Abstract

Questions that have been previously asked only in philosophical investigations, such as the nature of the self, have now become accessible to quantitative life and social sciences. Over the past decades, significant advances have enabled the cognitive neurosciences to study the neurocognitive basis of different aspects of the self, such as the affective self, the sensorimotor self, the ability to self-recognize and the distinction between self and other. The available neurocognitive data suggest that there is no single specialized neural system or a single neurocognitive function underlying selfhood. Instead, multiple unimodal and multimodal brain areas underlie distinct aspects of selfhood, such as the affective and sensorimotor self, the autobiographical and the social self. The discovery of a unifying neurocognitive basis of the self remains elusive, yet essential.

Introduction

Questions that have been previously asked only in philosophical investigations, such as the nature of the self, have now become accessible to quantitative life and social sciences. Over the past few decades, significant advances in research methods and experimental designs have enabled the cognitive neurosciences to study the neurocognitive basis of the self. However, the empirical study of the self is hindered by the multitude of selves described in psychological sciences. For example, Strawson (2009) counted up to 25 different forms of self, such as the 'cognitive,' the 'conceptual,' the 'core,' the 'embodied,' the 'empirical,' the 'interpersonal,' the 'material,' the 'narrative,' and the 'private' self to name a few. The fact that so many notions of self exist in psychology raises important methodological questions that require careful consideration when investigating how the self is represented in the brain. In addition, in similarity with other domains of information processing (e.g., language), questions of anatomical specificity (e.g., the existence or otherwise of self-specific areas or networks in the brain), functional uniqueness (e.g., whether the self is being processed in a unique way), functional independence (e.g., whether self-processing is independent from processing of other information), and species specificity (e.g., whether other species have a sense of self) are inevitably linked with current neuroscientific attempts to find the self in the brain.

A useful distinction often made in the neuroscience of self is between physical and psychological components (see Gillihan and Farah, 2005). The physical component corresponds to the affective and sensorimotor experience of one's own body, whereas the psychological component corresponds not only to the experience of one's own identity over time, but also to the experience of acting and interacting with the world. The importance of the distinction between the physical and the psychological components of selfhood lies in its applicability in neuroscientific research. Even though the physical and the psychological aspects are not experienced separately, they can be methodologically separated, enabling the empirical investigation of distinct subcomponents of selfhood, such as emotional self-awareness, awareness of one's own body and one's own actions, awareness of one's own identity over time and the awareness of the self as distinct from other people.

The Affective Self

The concept of an affective or 'core self' is based on the hypothesis that awareness of one's emotions plays a crucial adaptive role. The brain is constantly required to mediate between compelling demands arising from the internal milieu of the body, on the one hand, and the practical constraints of external reality on the other. Central to this negotiation between the inner and the outer is the neural processing of emotions that are closely linked to changes in the physiological states of the internal milieu. Feeling an emotion seems to be a simple matter, consisting of mental images arising from the neural patterns that represent the changes in the body that make up an emotion. However, having consciousness of that feeling, might have been the crucial step in the development of human self-consciousness because awareness of one's own emotions led to environmentally adaptive behaviors that went beyond simple automatic responses. The representation of internal body states is perhaps the most fundamental element of self-awareness, because the interoceptive system is used to remap via subcortical structures in the cerebral cortex the most stable aspects of the one's environment, that is, the organism's body (Damasio, 2010).

In line with this view, a primary 'core' quality of the self (Damasio, 2010) lies in the awareness of feelings that represent the affective interaction of one's own body with the environment. This type of awareness can be thought of as an inner sense directed toward one's own body, an idea going back to Locke, Brentano, and James. Interoceptive representations, that provide the content of this inner consciousness, include distinct feelings originating from the body, such as pain, temperature, itch, sensual touch, muscular and visceral sensations, hunger, and thirst among others. Recent neuroimaging studies attempted to study the neural correlates of interoceptive awareness. For example, Critchley et al. (2004) measured brain activity while participants judged the timing of their own heartbeat. Brain

activity in the right anterior insular cortex predicted the participants' accuracy at detecting their heartbeat. Converging evidence suggests that the insular cortex is responsible for representing interoceptive activity. These interoceptive representations of internal body-states seem to provide the basis for affective self-awareness. In addition to the insular cortex, other brain structures participate in the construction of first-order maps of the body, such as the hypothalamus, the brain-stem nuclei, and the somatosensory cortices. While these structures are used to represent body states, second-order maps, instantiated in the cingulate cortex and the thalamus are needed for integration awareness of the internal body with perception of external objects. These second-order maps will represent the relation between the inner and the outer world, serving an essential adaptive role.

The Sensorimotor Self

Another principal quality of the self is grounded in the experience of the body as a sensory and motor entity that belongs to 'me,' and that can be perceived not only within via interoception, but also from outside via exteroception. Two fundamental elements characterize this experience, the sense of body-ownership and the sense of agency (Gallagher, 2000).

The Sense of Body-Ownership

The feeling that the body I inhabit is mine and always with me is called body-ownership. Even though in everyday life the link between the body and its self is taken for granted, the cognitive and neural processes by which the body is experienced as linked to the self are far from being fully understood. Clinical cases of abnormal body-awareness aptly demonstrate the need for a neuroscientific account of the bodily self. Somatoparaphrenia is a neurological condition, which is usually related to anosognosia for hemiplegia, occurring after predominantly right hemispheric lesions. Patients with somatoparaphrenia believe that their limb contralateral to the side of the lesion belongs to someone else, and the disorder is often accompanied by inability to feel tactile sensations in the 'non-belonging' part of the body.

The rubber hand illusion (RHI) emerged as an experimental paradigm that allows the controlled manipulation of the experience of body-ownership. In brief, watching a rubber hand being stroked synchronously with one's own unseen hand causes the rubber hand to be attributed to one's own body, to 'feel like it is my hand' (Botvinick and Cohen, 1998). This illusion does not occur when the rubber hand is stroked asynchronously with respect to the subject's own hand. One behavioral correlate of the RHI is a change in the perceived location of the participant's own hand toward the rubber hand. Botvinick and Cohen (1998) showed that, after synchronous visuotactile stimulation of the rubber hand and the participant's hand, participants perceived the position of their hand to be closer to the rubber hand than it really was. Interestingly, the prevalence of illusion over time (Botvinick and Cohen, 1998) and the subjective intensity of the experience of body-ownership are positively correlated with changes in the felt location of the subject's own hand toward the rubber hand. Finally, the effects of multisensory integration between the rubber hand and the real hand have been shown to be specific to body parts, as synchronous multisensory stimulation between a non-corporeal object and the real hand does not lead to changes in body-ownership (for a review, see Tsakiris, 2010).

The RHI paradigm is one of the few viable ways of investigating body-ownership scientifically because it allows for an external object to be treated, rather than simply recognized, as a part of my body. The brain processes that produce the sense of body-ownership depend both on current sensory integration and also on the contribution of internal models of the body. The right temporoparietal junction (rTPJ) may underpin the assimilation of novel multisensory signals by maintaining a preexisting reference representation of one's own body. The rTPJ may underpin decisions about the incorporeability of external objects by testing the extent to which these objects fit with a reference body-model (see Tsakiris, 2010 for a review). The primary and associative somatosensory cortices seem to maintain online anatomical and postural representations of the current state of the body against which the anatomical and postural features of the stimulated object are compared. Body-related sensory integration linked to the onset of body-ownership during the RHI is related to activity in the posterior parietal cortex (PPC) and the ventral premotor cortex (Ehrsson et al., 2004). The effect of multisensory integration and recalibration of hand position, namely the experience of body-ownership of the rubber hand, has also been shown to correlate with activity in the right posterior insula (Tsakiris et al., 2007). Interestingly, a recent lesion mapping study that focused specifically on patients with somatoparaphrenic symptoms (Baier and Karnath, 2008) revealed that the right posterior insula is indeed the critical structure involved in phenomena of 'disturbed sensation of limb ownership.' Other authors have also suggested that the insula is concerned with higher order somatosensory processing of the body that is related to a subjective awareness and affective processing of bodily signals (Craig, 2009). The available imaging evidence on the RHI is consistent with the view that secondary somatosensory cortex and the insula are responsible for conscious somatosensory perception, with the right PPC contributing to spatiotemporal integration. Circuitry and connectivity analyses demonstrate both the afferent and efferent connectivity of the insula with SII, the temporoparietal area and the premotor cortex. These structures may form a network that plays a fundamental role in linking current sensory stimuli to one's own body, and thus also in self-awareness. Consistent results have been obtained more recently in studies that extended the RHI paradigm to full body illusions. As with the RHI, neuroimaging studies have implicated the premotor cortex and temporoparietal areas in the experience of illusory ownership over a full body (for a review, see Blanke, 2012).

The Sense of Agency

The studies on the sense of body-ownership highlight the importance of multisensory integration in creating a sensory sense of self. However, our bodies are first and foremost acting agents. The sense of agency is the sense of intending and

executing an action, a sense of oneself as an actor who can make things happen. One example taken from the psychiatric literature aptly illustrates how the sense of agency is linked to specific functional and neural processes. Schizophrenic patients with delusions of control demonstrate a striking failure to experience their own agency over the actions that they execute. The delusion of control is an example of a passivity experience in which a patient feels that his own actions are being created, not by himself, but by an outside force, usually an external agent. Increased activation in the right parietal cortex was related to the experience of passivity phenomena in schizophrenic patients (Spence et al., 1997). The main feature of this symptom is that the intention to act is misattributed to another agent, whereas the ownership of the body-part that executes the action is not.

At the neurocognitive level, delusions of control may arise as a result of an abnormal awareness of the predicted consequences of one's own action (Blakemore et al., 2002). An important aspect of agency involves the ability to distinguish actions and effects that are self-generated from those generated by other agents. The ability to distinguish between self-generated and externally generated events is embedded in the function of the motor system. In the case of a self-generated action, intentions and the efference copy of the motor command can be used to predict the consequent visual, auditory, and somatosensory signals produced by one's own movements. An internal 'forward model' of the motor system uses the efference copy of the motor command to predict the sensory effects of one's own actions. Once the actual sensory feedback arrives, it is compared with the prediction. If there is no mismatch between the predicted and actual feedback, the action is attributed to the self because the sensory event is recognized as being self-generated.

Several different experimental paradigms and clinical populations have been used to investigate the neural signatures of the sense of agency. Some have looked at the preaction processes, such as the formation of an intention and the preparation-selection of action, while others have focused on postaction processes that focus on the perception of action effects. A brain network that involves prefrontal and parietal areas has emerged as central to our experience of agency. In general, methods similar to the body-ownership literature, such as the systematic manipulation of visual feedback to alter the experience of one's body in action, have been used in agency research.

The supplementary motor area (SMA) is considered to be the brain structure responsible for translating motivational states originating from anterior cingulate cortex into intentional motor programs. SMA activity precedes M1 activation during the generation of voluntary movement (Deecke, 1996), and this activity is present even when a planned movement does not occur. Moreover, SMA activity seems to reflect a higher level representation of motor preparation and execution, as it is not correlated to the actual muscle activity. More direct evidence regarding the role of SMA in translating intentions into actions comes from Fried et al. (1991) who studied the functional organization of SMA in 13 patients with intractable epilepsy. Four patients who received direct electrical stimulation in SMA, below the threshold of afterdischarges, reported a subjective 'urge' to move or an anticipation that a movement was about to occur. At some of the sites where this 'urge to move' was elicited, higher current stimulation produced overt motor behavior. Overall, these observations argue in favor of Goldberg's view that SMA functions in a 'supramotor' fashion, and that it "is being engaged earlier than M1 in the translation of motive to intention to action and exerting control over M1" (Goldberg, 1985).

Given that a certain goal can be achieved in various ways, the selection of the motor program that will be executed is a central problem in the generation of intentional actions. When people are asked to perform open-ended willed actions, increased activation in the left dorsolateral prefrontal cortex (DLPFC) was found, as opposed to when people perform routine acts as response to stimuli. Such findings suggest that the DLPFC is 'sculpting the response space' from which then we can actively choose an action according to our own will (Frith, 2000).

In addition to these frontal areas, the parietal cortex is also involved in our sense of agency because of its multimodal role, whereby both efferent and multimodal afferent signals converge in order to represent accurately the current state of the organism in relation to its environment. Andersen and Buneo (2002) argued for the presence of various 'intentional maps' in the PPC, which correspond to specific goals for orienting actions. The common functional principle of the PPC is to transform multisensory signals into appropriate motor plans or 'motor intentions.' Parietal cortex is also involved in the online monitoring and perception of actions and their consequences. Fink et al. (1999) investigated the neural responses during a conflict between the intention to move and the afferent feedback. In some trials subjects performed out-of-phase bimanual movements, but they saw in-phase movements. The main effect of out-of-phase movements (i.e., a mismatch among intention, proprioception and visual feedback) was associated with increased activity in PPC and DLPFC bilaterally. It seems therefore that parietal cortex plays a pivotal role in detecting mismatches between the intended and the actual movement, especially in cases where there is ambiguous visual feedback. The parietal cortex functions as a neural workspace that facilitates the integration of efferent, reafferent and ex-afferent signals. Overall, it has been suggested that the intact function of frontoparietal neural loops is necessary for the generation, execution, and perception of intentional actions, processes that are essential for the normal experience of agency.

Self-Recognition

The face is the most distinctive feature of our appearance, the one by which we come to be known to ourselves and to others as an individual. The importance of faces to the self-concept and for social cognition leads to their physical features being processed in a specialized neural circuit. In turn, there is some evidence to suggest that representations of one's own facial appearance may be stored in a similarly specialized network of areas, which is engaged when a face that is recognized as one's own is processed (Devue and Bredart, 2011). In a typical self-face recognition experiment, participants are presented with

pictures of morphed faces that contain varying degrees of the participants' face and the face of another person with whom the participant was personally familiar (e.g., 0, 20, 40, 60, 80, or 100% of the participant's own face), and participants are asked to judge whether the face looks more like their own or not. A study by Uddin et al. (2005) reported that portions of the inferior parietal lobe (IPL) and inferior frontal gyrus (IFG) showed a parametric response, increasing with the amount of self-face in the stimuli. They also reported activity in the ventromedial portions of the frontal lobe, the precuneus, the superior frontal gyrus, the superior parietal lobe (SPL), and medial portions of a region covering the right inferior temporal gyrus (ITG) and the right middle temporal gyrus (MTG), which showed an increasingly negative response the more that stimuli contained of the self-face. A recent review of the literature highlights that these regions are those that are typically reported as activated in studies that investigate the neural basis of current self-face recognition (Devue and Bredart, 2011). More recently, Apps et al. (2012) used functional magnetic resonance imaging to investigate the neural circuits involved in the recognition of the different faces of one's self. Participants viewed images of either their own face as it currently looks morphed with the face of a familiar other or their childhood face morphed with the childhood face of the familiar other. Activity in areas that have a generalized selectivity for faces, including the inferior occipital gyrus, the superior parietal lobule, and the ITG, varied with the amount of current self-face in an image. Activity in areas involved in memory encoding and retrieval, including the hippocampus and the posterior cingulate gyrus, and areas involved in creating a sense of body-ownership, including the temporoparietal junction (TPJ) and the inferior parietal lobule, varied with the amount of childhood self in an image. Therefore, recognizing one's past and current facial appearances relies on processing in distinct neural circuits. Recognition of one's physical appearance from the past engages areas involved in body-ownership and recognition memory. This suggests that identifying a past facial appearance as one's own requires the physical features of the face to be retrieved from memory and coded for as a part of one's body. In contrast, a representation of one's current self-image is maintained and updated through plastic processes in areas of the brain that are specialized for processing faces, but not specifically one's own face. These findings pave the way for understanding the neural mechanisms underlying the plasticity of self-representations as a result of changes in appearance due to normal aging as well as due to traumatic events or reconstructive surgery.

More general, self-face, voice, and body recognition have been shown to activate unimodal regions within the core face processing network including: the inferior occipital gyrus, the fusiform gyrus, as well as face selective areas in the superior temporal sulcus (STS), portions of the auditory system in the superior temporal gyrus, and portions of extrastriate cortex that process body parts. However, it is well established that these areas process information about all faces, bodies, or voices, even if the profile of their response is different between self and other. Such findings would suggest that these regions are not processing anything that is specific to the self. Neuroimaging studies suggest that unimodal self-face, voice, and body recognition also activate a broad range of multimodal areas. The list of areas includes: the posterior cingulate gyrus, the anterior cingulate gyrus (ACG), medial portions of the superior frontal gyrus/paracingulate cortex, the TPJ, the STS, the temporal poles, the hippocampus, the anterior insula (AI), midportions of the IFG, the middle frontal gyrus (MFG), the intraparietal sulcus (IPS), and the inferior parietal lobule. Some have therefore argued that information processed in some of these regions is self-specific and it is processing in these areas that leads to a self-concept (Northoff et al., 2006). However, there is little evidence that these regions are engaged exclusively by self-recognition processes and indeed, each of these regions is not found to be activated exclusively during the processing of self-stimuli (Legrand and Ruby, 2009).

The Self-Representing Self

Our psychological sense of self-identity seems to be grounded in explicit and conceptual representations, such as one's own memories, personality traits, beliefs, and attitudes. A sense of identity over time is given by autobiographical memory. Research on autobiographical memory has not provided a definite answer as to whether autobiographical memory is functionally independent from other memory systems. Neuropsychological case studies demonstrate that it is possible to have intact autobiographical memory despite severe impairment in semantic memory system. Similarly, the evidence for specific neural correlates of autobiographical memory is inconclusive. The overall pattern across studies suggests that retrieval of autobiographical memories is associated with activations of medial frontal cortex and the left hippocampus (for a review, see Maguire, 2001). However, many of the studies have failed to control for various confounding factors between autobiographical and other memory systems (for a review, see Gillihan and Farah, 2005). Importantly, autobiographical memory provides both a sense of continuity over time and a sense of identity. The sense of continuity over time is given by the fact that autobiographical memory provides a template of the past against which new experiences can be assimilated. The sense of identity is generated by the fact that all these experiences are related to me, rather than to someone else.

Social cognitive neuroscience has focused on the neural circuits that are common to both self- and other-representations, which may be critical for social cooperation and empathy. A meta-analysis of the functional anatomy of action-execution, mental simulation of action, verbal generation of actions, and more importantly observation of other people's actions showed that for all four processes, overlapping activation was found in SMA, dorsal premotor cortex, supramarginal gyrus, and SPL (Grezes and Decety, 2001). The activation of an overlapping neural network for both the representations of self-generated and observed actions suggests that some representations are agent-neutral and shared. More evidence for common representations for self and others comes from the neural substrates of empathy. Bilateral AI, rostral anterior cingulate cortex, brainstem, and cerebellum were activated when participants received pain and also when a loved one experienced pain (Singer et al., 2004). The

existence of an overlapping neural network, or 'mirror system' that underpins both self- and other representations may support social communication and interaction. This discovery raises the interesting possibility that some aspects of the awareness of self resulted from mechanisms that initially evolved through attempts to predict the behavior of others through representing their internal states and justifies the claim that perhaps consciousness is for other people.

Future Directions

The available neurocognitive data suggest that there is no single specialized neural system or a single cognitive function underlying selfhood. Instead, multiple specialized processes underlie distinct aspects of selfhood, such as the affective and sensorimotor self, the autobiographical and the social self. These specialized processes operate at a sub-personal level and they may not be accessible to conscious awareness. The cognitive neuroscience of self is faced with the challenge of explaining how these specialized processes interact at the functional and neural level to generate a coherent and conscious sense of self.

Current empirical studies on the sense of self focus on either the physical or the psychological dimension of selfhood. Indeed, there seems to be a real difference between sensorimotor theories of self and most psychopersonal theories of self as regards the continuity of personal identity over time and autobiographical memory. Our sense of embodiment seems to be immediate and transient, while a reflective and autobiographical sense of self seems to be stable over time. Future studies need to address the neurocognitive processes that bridge the physical and the psychological dimensions of selfhood and provide a unifying neurocognitive theory of self-processing.

Self and Emotional Development in Adulthood and Later Life

Gisela Labouvie-Vief, University of Geneva, Geneva, Switzerland

Abstract

Attention to the development of emotions and self in adulthood and aging has dramatically increased in the past half-century, and different theoretical frameworks have been presented to deal with the resulting findings. The current article reviews the major positions to have addressed these findings, and presents a view that details both strengths and vulnerabilities related to self and emotions. Thus in settings that are novel and familiar, the capacity to deal with situations of high complexity and tension is negatively affected by the process of aging; this vulnerability is offset if individuals can base themselves on skills that have been well developed and crystallized. The present article discusses these general changes over the adult life span by suggesting that while earlier development of self and emotions is characterized by an increasing capacity to deal with tension, that capacity becomes compromised and the source of vulnerability in the later part of the life span.

Introduction

Emotions are of importance throughout the total life span, from birth to late life. They play an important role in diverse areas of life. As important adaptive systems, they steer our actions in one direction or another, depending on critical circumstances. Depending on our ability to modulate and regulate them, they afford us a sense of personal well-being or lack thereof. They are of prime importance in social relations and thus constitute a basic element of our functioning within kinship and cultural systems (Magai, 2001). And finally, they constitute an important basis to our personality and sense of self.

There has been, as a consequence, much interest in the nature and development of emotions. Yet until recently, the majority of work on emotional development concerned itself with processes from infancy to childhood and adolescence. Many pioneer theories held, in fact, that development was, in essence, completed sometime around the entry into early adulthood, with little change thereafter (see Labouvie-Vief, 1994). But with increasing interest in theory and research on adult development, there has been a burst of interest in development in mature and later life as evidenced by the contributions of theorists such as Carl Gustav Jung (1933) and Erik Erikson (1978). Currently, a number of theoretical frameworks on emotional development in adulthood and later life have emerged; these frameworks offer partially convergent and partially divergent interpretations of certain aspects of mature adulthood and later life. In the present contribution, I outline several approaches to describing emotional development and discuss how they bear on processes of individual and interpersonal adaptation. I summarize, as well, a theoretical approach that is able to reconcile some of the interpretive divergences by means of a cognitive-developmental theory that provides a coherent description not just of a single period of life, but of the total span of life from birth to old age.

Theoretical Approaches to Emotional Development

Differential Emotions Theory

Emotions as Core Adaptive Survival Responses

Emotions have had a problematic status in Western intellectual history since Greek philosophy due to their inherent subjective nature. In contrast to cognitive/intellectual functions, they often were maligned as undermining our ability to behave in a well-reasoned and rational fashion (see Labouvie-Vief, 1994). While it is true that rational clarity tends to be clouded in the heat of passion, a more modern stance is to point to enormous adaptive importance of emotions in virtually all of human and animal life. This claim of the importance of emotions was introduced by Darwin, who in the wake of his theory of evolution proposed, in *The Expression of Emotion in Man and Animals* (Darwin, 1965/1882), that emotions had an extremely important function in survival and adaptation. Just like the bodily structures of primary importance in his theory of evolution, he held that emotions, too, had been established by evolution to assure that in emergency situations (for example, threat by another animal) highly automated systems of responding would ensure quick survival responses (e.g., flight or counterattack). How to cope with such highly urgent situations hence did not depend on processes of reflection, which tend to be costly for survival because they can involve too much time and conscious effort. Instead they drew on response systems that were highly automated and rapid. Darwin described different such response systems that were shared by animals and humans alike.

Darwin's theory provided an important base for scientific study of emotions. His proposal that different emotional systems were adapted for different purposes became the basis of differential emotions theory (e.g., Izard, 1971, 1977; Ekman, 1973; for review, see Magai, 2001). Following Darwin's suggestions, this theory proposed that there exist qualitatively different primary or basic emotions, such as anger, joy, sadness, fear, shame, or disgust. Each of these emotions was characterized by a specific pattern of eliciting conditions, along with distinct patterns of expressive (physiognomic and gross motor) as well as physiological response patterns.

Whereas, following Darwin, differential emotions theory has dealt with emotions on an individual level, emotion systems may be more complex and encompass the synchronization of emotional responses among individuals. An example of much recent interest is the emotion system of empathy (DeWaal, 2010). Although this system exists in a uniquely mature form, its developmental precursors are completely automatic, involving such responses as mimicking the mood of

 http://dx.doi.org/10.1016/B978-0-08-097086-8.26021-2

another through unconsciously moving our body in synchrony, as a result of which we partake in the emotional state observed.

One example particularly important from a developmental perspective is the attachment system discussed by John Bowlby (1973), a psychoanalyst who offered an ethological theory proposing that the mother–child bond had an evolutionary base because of its important survival function. To secure the survival of the young, there must be in place a repertoire of instinctual behaviors whose aim is to seek and to maintain proximity with parents, and especially to seek it in all possible situations of emergency. Ideally, such systems function in mutuality and reciprocity, but development also can bring problematic deviations from genuine mutuality. Some of such deviations are of importance in interpreting emotional responses along the total of the life span, as will be discussed more fully later.

Stability and Change of Primary Emotions

It is a general assumption of the differential emotions approach that emotional systems are in place early and remain stable throughout the life span. The importance of such stability is that it provides consistency of the adaptive aims that are subserved by the basic emotional systems. In addition, stability is crucial for a sense of self that is experienced as continuous, as opposed to one that is characterized by confusion of self and identity. In this way, emotions also become an important part of the gradual elaboration of the personality.

The core stability of emotional aspects to self and identity is not rigid, however; change is possible, as well, and with increasing development, the basic response patterns become enriched by, and interlinked with, other response systems. For example, with the growth of cognitive understanding and development, individuals become better able to differentiate the experience of self from that of others, and more adept at functioning in reflective ways that permit modulation and regulation/control of experience. Some of these changes will be discussed more fully in the section on cognitive-developmental approaches to emotional development.

Other changes in the nature of primary emotions may be due to biological changes that are apparent across the life span. For example, Sroufe (1996) studied the prototypical emotional responses of laughter and its developmental precursor, smiling, over the course of the first 2 years of life. Smiling is a low intensity response that in newborns appears as a reaction to purely internal stimulation. Over the course of the first four or so months, smiling responses become gradually quicker and more active, and more explicitly related to external events. At first, the elicitors are of low intensity, such as gentle speaking or touching, but eventually they become more dynamic, as becomes the expression of smiling, itself. After 4 months of age, in contrast, one typically observes a much more active laughter, a dynamic and vigorous response characterized by sound bursts and active movements in response to complex and highly dynamic stimuli. On the basis of his work, Sroufe proposes that early development of smiling and laughter involves an increasing capacity to tolerate and enjoy stimulation of high intensity, novelty, and complexity – stimulation that at earlier stages produces fear and distress, a result of too-high levels of tension. In fact, Labouvie-Vief proposes that the resulting lowering of tension thresholds and capacity to not even tolerate, but even embrace high levels of tension is one general characteristic of positive emotional development (see Labouvie-Vief et al., 2014).

Responses to varying levels of intensity have also been studied in adults and older individuals, and a number of studies report that the intensity of affect and the strength of impulses is lower in later life (although other studies report the opposite) (see Blanchard-Fields, 2009 and later discussion). It is not entirely clear why this should be so, but different explanations are apparent. For example, it is evident that older individuals, as a result of their accumulated experience, have become experts at regulating their emotions (Blanchard-Fields, 2009). Another explanation, to which we will return later, points, instead, to evidence that high-level stimulation becomes more difficult to tolerate and sustain for individuals in their later life; hence they have come to key in to stimulation that is less intense and more comfortable. Such changes in preference may root in basic biological changes that make regulatory efforts more difficult, as detailed later.

Hedonics of Emotions: Processes of Emotional Control and Optimization

Differential emotions theory had as its primary objective the precise, scientifically valid description of emotional processes. Another major interest has been in the question of how individuals come to regulate their emotions so as to maintain their levels of tension and arousal within acceptable levels. These approaches often take as important criteria those of well-being, such as an overall positive as opposed to negative affect tone. Here, core questions are whether individuals are able to ward off emotional stimulation that is overactivating and stressful and experienced as negative, and instead strive for, and maintain, a sense of positive well-being.

Optimization and Emotional Selectivity

Whereas aging often is construed in popular culture as a period fraught with difficulties and losses, research has tended to show that older individuals often report high levels of well-being (for review, see Fung et al., 2005). One major explanation of this apparent paradox has been proposed in Carstensen's (see Carstensen et al., 2006) social-emotional selectivity theory. This theory proposes that with increasing age, older individuals come to change their values and goals. The core reason for this change is that, unlike youth, they develop a sharpened sense of the passage and limits of time. What seems like a vast expanse of time for the young, for the aging individual comes to be experienced as time left to live. This restructuring of time, in turn, is related to a restructuring of goals and values.

According to emotional selectivity theory, time for the young is experienced as unlimited. As a result, young adults are primarily invested in goals that emphasize preparation for future success, with knowledge seeking goals being particularly evident. Older adults, in contrast, are said to experience a goal shift toward emotional and interpersonal satisfaction. They aim at optimizing pleasure and satisfaction, and they do so especially in terms of focusing on satisfying and meaningful

interactions while abandoning those that are too stressful. Thus, they appear to actively orient toward optimizing positive feelings and avoiding and decreasing negative ones. In part, they do so by trimming their social networks, restricting them more and more to the most intimate and satisfying relationships.

In support of the notion of optimization of positive emotions, emotional selectivity theory points to a plethora of findings; Kryla-Lighthall and Mather (2008), for example, cite an impressive body of research. First of all, a series of studies has demonstrated that, in general, older individuals report quite high levels of well-being, with decreased negative and increased positive affect as compared to younger adults. Nevertheless, reports are not always consistent; some studies find decrease in negative emotions such as anger over the adult life span, while others report stability of negative affect. Older adults also do appear to experience a shift in their emotional goals. For example, time spent with acquaintances and close friends declines, whereas that spent with close family members increases. In general, elders place high value on social relationships and positive contributions to society, in contrast to younger adults who are more likely to describe life goals such as emphasis on learning and taking new challenges. Elders instead direct considerable attention to optimizing positive affect and to redirect attention away from negative information. As a result, they often display superior emotion regulation strategies, especially ones that are aimed at avoiding and bypassing interpersonal conflict rather than strategies of confrontation that are likely to it.

Attachment Theory as an Explanatory Framework for Selectivity

As indicated, emotional selectivity theory has created an impressive body of research to demonstrate selectivity of emotions. Nevertheless, it is not always evident exactly how and why individuals come to optimize reports of positive emotions, because reporting positivity does not always indicate good regulation skills. Sometimes, indeed, it points to a tendency to downplay difficulty with regulation. Hence there may exist different motivational bases for reporting positivity. Attachment theory, briefly outlined previously, has addressed this ambiguity by defining different styles of attachment, each of which indicates different reasons for why individuals may seek out and/or report positive relations based on the observation of brief periods of separation from the mother (for review, see Mikulincer and Shaver, 2010): these styles have also been extended to and validated for adult populations.

In young children, a *secure style* is evident if, upon reentry of the mother, children do not avoid contact with her by turning away in anger, but approach to her and, if necessary, let themselves be consoled. In contrast, an *avoidant-dismissing* style is evident in children who avoid contact with mother upon reunion and do not reestablish contact with her; these children apparently adopt an air of apparent indifference and calm through remaining distant as a way of adapting to frequent problematic interactions with mother. *Fearfully attached* children, in contrast, are difficult to accept mothers' attempts to comfort them: they vacillate between anger and approach, indicating a relationship that is ambivalent at its core.

As noted, similar attachment styles have been established for adults by means of attachment style questionnaires. Again, research established that the motivations for displays of positivity are very different for the different styles (Mikulincer and Shaver, 2010). *Secure* adults display a positive approach toward and evaluation of self and others. *Dismissing* adults, in contrast, describe themselves in a positive fashion, but project their motives of avoidance on others whom they describe in a negative fashion. *Fearful* adults, finally, tend to describe others as rather positive, but themselves as more negative.

Mikulincer and his colleagues have conducted a series of studies that show that, especially in the case of secure and avoidant-dismissing individuals, different motivations underlie the overt display of positivity. For secure individuals, positivity appears to be a genuine, effortless expression, but for avoidant-dismissing adults, positivity is achieved through the repression of negativity by means of effortful cognitive distortion. This process is evident in experiments that require the judgment of the positivity or negativity of targets (e.g., pictures), and compare conditions in which no special effort is required to ones in which individuals also need to pay attention to other, effort-demanding tasks. Under such conditions, the positivity effect found among dismissing adults is canceled, and instead, avoidant/dismissing individuals evidence a dramatic rise in negative responses. The same reversal is not, however, evident in secure individuals. Such findings are interpreted as the presence of a powerful motivation toward *avoiding negative experiences*, rather than an *effortless orientation toward positivity*.

Interestingly, the reversal indicated has been reported by Mather and Knight (2005; see Kryla-Lighthall and Mather, 2008) who found a positivity effect in older adults' memory for pictures when individuals could direct their full attention to viewing pictures; in contrast, when individuals were distracted by means of a second effort-demanding task, this positivity effect was dramatically reversed, indicating a lowering of positive but a dramatic rise of negative responses. This finding supports the proposed interpretation of a negativity-avoidant motivation as opposed to one that is able to effortlessly seek out positivity.

Avoidance of negativity rather than genuine positivity also has been reported in Labouvie-Vief's (Labouvie-Vief, 2008) research. Among elders who reported positive affect, one subgroup also reported that they had a secure relationship style. This group also displayed high tolerance for ambiguity and affect exploration. In contrast, another subgroup placed little emphasis on openness but scored higher on conformity, denial, and repression. Of all of the elderly, this group also scored particularly low on empathy. Hence it appears that reports of high positive and low negative affect can imply very different core motivations – that of affirming positive affect, as opposed to that of avoiding negative affect. We will return to this finding in the next section on cognitive-developmental interpretations of positivity phenomena, proposing an interpretation in terms of unique vulnerabilities that emerge as part of the process of aging, and that render avoidance of negative experiences and stress especially important.

Cognitive-Developmental Theory

A third theoretical position to the study of emotions and self in aging has been developed by Labouvie-Vief (Labouvie-Vief and Marquez, 2004; Labouvie-Vief et al., 2009, 2010, 2014). This work began with the observation that approaches to the study of aging often have developed out of context of that of developmental processes of earlier life. Gerontology was established only about in the middle of the twentieth century, and emotional development in adulthood and later life began to enjoy popularity only since the later part of that period. The study of emotion began early with the work of Sigmund Freud and continued with that of Piaget (1991). Both theoreticians offered theories that focused not just on stage-specific descriptions of developmental phenomena, but were strongly interested in how mature emotions emerged gradually from precursors that were rather immature, involuntary, and reflex-like. Freud proposed that such primordial emotional responses were characteristic of 'primary process' functioning of the ID, but that with mature development, such processes were gradually encompassed, amplified, and even governed by the more conscious executive mechanisms of the ego. Both theoreticians hence proposed a view of emotional development as a series of transformations in which more unconscious and automatic processes begin to interact with more deliberate and conscious ones. This process of transformation implies a series of processes on neurobiological and cognitive processes that transform emotions from lower to higher levels of complexity at psychological and biological levels.

Cognitive and Neurobiological Mechanisms of Emotional Transformation from Childhood to Adolescence

As already pointed out, emotions and cognitive-rational functions often have been described as existing in a state of tension and polarization. One developmental psychologist who rejected such polarization was Piaget (e.g., 1991) who suggested that although the systems subserve different functions, these two are intimately linked. On that view, emotions have a dynamic and energetic function (as evident, in fact, in the Darwinian notion of affect earlier discussed). In contrast, cognition has a structural function that is oriented toward stability and equilibrium. The great Soviet psychologist Luria demonstrated in the 1930s (Luria, 1932) that the use of language acted to dampen the peripheral arousal and motor excitation that characterizes strong emotions. More recently, research has established that the use of linguistic labels function to downregulate (reduce and control) activation of brain regions involved in emotional arousal (see Labouvie-Vief et al., 2014). Thus, merely labeling emotional faces decreased activity of the amygdala, the core related to emotional arousal; at the same time, the inhibitory/control areas of the prefrontal cortex increased in activity.

Piaget also proposed such intimate interplay when stating "if our … hypotheses are correct, we shall be able to parallel, stage by stage, the intellectual structures and the levels of emotional development. Since no structure exists without dynamic and since, respectively, a new from of energizing regulation must correspond to any new structure, a certain type of cognitive structure must correspond to each new level of emotional behavior" (Piaget, 1954: 10, as quoted in Labouvie-Vief and DeVoe, 1991).

Accordingly, Piaget proposed a series of cognitive-emotional stages from birth to adolescence (see Labouvie-Vief and DeVoe, 1991). At birth, the cognitive-emotional repertoire consists of hereditary organizations such as reflexes, instinctual drives, and affective reactions present at birth. However, these soon become reorganized as a function of learning, as children link emotions with events they have experienced and thus attach to them the satisfaction or disappointments of expectations. In toddlerhood (Piaget's preoperational stage), language and representation emerge, which allow stabilizing and controlling feelings. This emerging capacity for control becomes stabilized as school-age children come to understand and internalize social rules for emotional expression and accordingly regulate their behavior along their understanding of what is socially acceptable. This capacity for internally oriented control becomes even more effective in adolescents who develop abstract thought that permits to construct ideals of how affect should be felt and regulated.

In addition to emotional controls, emotions themselves become more complex in the course of development. One example is the emotion of empathy mentioned earlier. This emotion develops out of simple precursors that reflect automatic responses of mimicking and emotional contagion to the distress of others. It is hence primarily related to the distress induced in the self when watching another. However, to come to be able to effectively offer aid to the other in distress, the development of a set of cognitively complex skills is required: the self needs to be able to differentiate the state of the other from that of the self so as to be able to imagine the other's suffering as a separate state. This, then, represents a complex cognitive operation that, in its mature form, emerges only gradually over the course of the life span, and parallels the development of complex cognitive understanding (see Labouvie-Vief et al., 2010). Only once individuals have come to master these skills, is it possible to display genuine empathic concern for others.

The emergence of such complex skills related to emotions and self-representations has been the focus of a considerable body of neurobiological research (see Labouvie-Vief et al., 2014). At the beginning, capacities for emotional regulation draw upon brainstem-related automatic homeostatic mechanisms that permit an original foundation for the automatic regulation of emotional state. Over time and with continued cortical growth, these areas become richly interconnected with the growth of higher cortical centers implicated in control and inhibition, permitting the adaptive control over states of tension and stress. At first, rather effortful and based on attention-demanding engagement, these capacities themselves become well automated or crystallized with practice, and hence are performed with decreasing effort. This process of automatization/crystallization hence implies that the modulation and tension reduction at more mature stages is accomplished by the automatization of processes that require effort at younger ages. Hence with increasingly complex cognitive skills and more complex neurological interconnections of

Figure 1 Levels of emotional understanding from preadolescence to late life. Reproduced by permission from Psychology and Aging, 1989, 4 (4), 425–437.

brain functions, individuals can readily master levels of activation and stress that previously were difficult and stressful. This process of lowering of tension thresholds with increasing complexity of cognitive and neurological processes is, in fact, the major result of positive development up until at least middle adulthood. How, then, does this process continue in later adulthood and aging?

Cognitive and Neurobiological Mechanisms of Emotional Transformation in Adulthood and Later Life

Piaget's general scheme of cognition–emotion relations has had a profound influence on childhood researchers of emotional development. From the perspective of adulthood, however, these capacities can have a highly conventional cast that is not ideally suited to continued development in mature and later adulthood. For example, Jung (1933; see Labouvie-Vief, 1994) proposed that the internalization of rules and norms and the constraints of institutions in the first part of life results in an overly mental and outer-directed orientation in which individuals must devalue much of their inner life as 'childish' or 'immature.' In contrast, the goal of mature and later adulthood is said to be to free oneself from these restrictions and idealizations and to explore and liberate deeper, richer, and more complex layers of the personality. A researcher who has specifically used this notion of expansion of the self and emotions was Jane Loevinger who in her theory of ego development (for a summary see Labouvie-Vief, 2002) proposed such movements from conventionality to ways of thinking and being that cherish individuality, self fulfillment, and the psychological depths of one's personality – its causes, apparent contradictions, and paradoxes.

What is the evidence for such continued developmental movements? Labouvie-Vief (see Labouvie-Vief and DeVoe, 1991) applied these notions to the development of conceptions of emotions and the self. Adolescent to adult individuals ranging in age from about 16 to the mid-80s described their experience of emotion in a first study, and of their self in a second. In both, responses were transcribed and coded into four levels, ranging concrete-presystemic to dynamic-intersubjective. At the simplest level, individuals gave global and concrete responses that simple actions, physical characteristics, but do not mention motivational processes (e.g., 'I am nice,' 'I am pretty,' etc.). At the dynamic-intersubjective level, in contrast, individuals vividly described interpersonal dynamics, and were aware of psychological processes and motivations that played a role in the biographic emergence of their personality (e.g., "I struggle with the concept of who I am and have been identified (all giving mother, self-sufficient, religious) and I think, feeling the need to be a more individualized woman with specific needs and desires").

Results showed the hypothesized growth in complexity of descriptions of emotions and (see Figure 1) and self (see Figure 2) from adolescence to late midlife; surprisingly, however, these trends did not continue past the late midlife period but rather showed an apparent reversal, with lower levels reached by older individuals in a study done quite independently. Similar results also emerged when assessing

Figure 2 Levels of self-representations from preadolescence to late life. Reproduced by permission from Psychology and Aging, 1995, 10 (3), 404–415.

Figure 3 Twelve-year longitudinal gradients of ego development from preadolescence to old age.
Reproduced from Grühn, D., Diehl, M., Lumley, M., Labouvie-Vief, G., July 2008. Paper Presented at the 29th International Congress of Psychology, Berlin, Germany.

levels of ego development, as indicated in Figure 3. Moreover, in contrast to the first two studies, which were cross-sectional, the third reflects longitudinal data. Despite the differences in measurement and methodology, however, the results are very consistent.

These results were encouraging in the sense that, as expected, the process of cognitive-emotional integration became increasingly more complex and well integrated from adolescence to mid-adult life and that this process was evident across several different criteria of complexity. In contrast to middle adulthood, however, evidence did not suggest continuation of a similar process of continued growth and integration from that point onward. These results were disappointing in the sense that, at least by the criteria used, older adults did not adopt a similarly complex and rich approach to talking about self and personality. Since the measure of this work was strongly oriented toward aspects of cognitive complexity, the obvious question is, do such results suggest that cognitive changes often affected with aging are the culprit for such apparent declines?

The answer to this question is both yes and no. First, it is widely established that aging brings normative declines in certain cognitive functions. These functions can constrain further development as certain cognitive-emotional processes become less efficient and more effortful. On the other hand, elders bring to many tasks a rich repertoire of knowledge they have established and crystallized as a result of a lifetime of experiences. In tasks that permits them to apply such knowledge toward the solution, they often maintain superior performance and can evidence high levels of wisdom (see Labouvie-Vief et al., 2010) – a result of having available preexisting well-automated though often quite complex skills (Blanchard-Fields, 2009). However, the changes in the cognitive system are most relevant in tasks that make high demands on the processing system because they are relatively novel and not yet well integrated into an already established repertoire of cognitive-emotional skills. In contrast, novel experiences that require the formation of such complex skills *de novo* pose particular problems to the elderly; this is especially true of tasks that are of unusually high levels of difficulty, if they require that one disregard highly exercised and automated skills in contexts that are not appropriate, or if individuals are required to perform under levels of raised activation or even stress, or ones of unusually high levels of difficulty.

As a result, the picture of aging and emotion experience and regulation offers two rather distinct pathways. One indicates a pattern of vulnerabilities in situations that are novel or relatively high in stress and arousal. The second, in contrast, offers a picture of well-integrated emotion experience and regulation in contexts in which older individuals can base themselves on their rich background of well-crystallized emotion experience and knowledge.

The literature relating to these dual pathways has been extensively summarized by Labouvie-Vief and her collaborators (Labouvie-Vief and Marquez, 2004; Labouvie-Vief et al., 2009, 2010, 2014). A brief summary of the related evidence follows below.

Vulnerability of Later Life Regulation Capacities

As stated, vulnerabilities and restrictions in emotion regulation have been widely documented in situations that exceed individual's accustomed level of complexity, or that require inhibition of well-automated functioning. A number of functions are affected in such situations. *First*, in light with the notion that tension thresholds become lowered in later life, older individuals do not tolerate highly arousing situations well, and consider highly arousing material to be negative. *Second* and relatedly, this lowered tolerance for high tension tends to be disruptive in older adults' cognitive performance, whereas young adults are quite impervious to variations in arousal.

A *third* line of recent evidence suggesting that the aging system is more easily overwhelmed emerges from research using physiological measures of effort, such as systolic blood pressure and cardiovascular stress, and indicating that difficult cognitive challenge places greater physiological stress on elders' system. Such heightened stress is particularly likely in situations of competition or other added stress for the elderly, whereas younger individuals may even be stimulated by such situations.

Fourth, physiological research also indicates that older adults show more pronounced stress-induced hormonal secretion than younger adults during a cognitive challenge. They also take more time to recover from such stress-related reactions than younger adults. Indeed, studies on stress provide further evidence for the greater dysregulation of the system under high levels of arousal and/or effort with advancing age.

Fifth, older individuals are especially negatively affected by conditions of challenge and stress. For example, in a series of studies, older individuals do worse than young individuals on their performance on cognitively challenging task, particularly if these tasks are novel.

Finally in a series of studies examining the relation between attachment styles and emotional reactivity in older individuals, elders with an avoidant dismissing attachment style did fare better than other elders. However, when the situation was particularly activating, such as engaging in a discussion about a conflict, older avoidant, dismissing women had higher initial heart rate and slower recovery rates than their peers. These

results suggest that a dismissing style can serve a partially protective role for some older individuals, but not when levels of activation reach a critical level. Consistent with this proposition, several studies (see Labouvie-Vief et al., 2009; Magai, 2001; Zhang and Labouvie-Vief, 2004) have shown that the avoidant-dismissing, self-protective style of attachment just described is more prevalent in the elderly than in younger adults, suggesting that this style may reflect an attempt to use compensatory protection strategy against negative emotions and their consequences (Labouvie-Vief et al., 2009).

In summary, increasing age and reduced tolerance for high tension seems to impair the capacity to cope with high complexity emotional information. Nevertheless, this loss can be set off by the availability of strong crystallized processes that provide a protective function.

Aging and Crystallization: Strengths of Later Life Regulation Capacities

In contrast to the more problematic aging changes just discussed, a number of studies on aging suggest that automatic functioning seems little affected in later life and may even increase in importance. More specifically, preserved automaticity is likely to aid individuals' performance in situations or tasks that do not require them to inhibit their well-automated cognitive-emotional knowledge, and in tasks that are in the range of complexity for which such crystallized knowledge already is available. Indeed, effects usually associated with aging – such as reduction of cognitive control over emotions – are not always detrimental, but actually may bring positive benefits to the extent that automated knowledge systems may provide a rich base for integrating experience.

Deepened Inner Orientation

In the eyes of some theoreticians, increases in automatic functioning in later life may bring unique benefits to the aging person. Jung (1933) suggested long ago that with a relaxation of controlled functioning, mid- to late adulthood can bring a liberation of unconscious processes and with it, a turn away from preoccupations with the outer world. Instead, the resulting increases in understanding inner layers of experience may achieve their height in later life, through a process of 'centroversion' toward the inner world (see Labouvie-Vief, 1994).

One sign of this inward shift is a general way in which individuals' relationship to information becomes restructured. For the young adult, information is seen as an outer given that one attempts to reproduce in a literal way. In contrast, middle and older adults turn more to the landscape of human motivations and intentions. Hence, they may become experts at the processing of information relating to subjective processes and inner dynamics. Although this symbolic processing style can result in reduced attention to the literal level, it may imply a richer psychological texture. Indeed, a series of studies reviewed elsewhere (for review, see Jepson and Labouvie-Vief, 1992) suggests that older individuals continue to develop highly integrated and personally meaningful insights about life's regularities – the hallmark of advanced wisdom.

Somewhat relatedly, a growing body of research suggests that age differences can diminish or even disappear if experimental tasks permit the elderly to make use of the inner orientation that draws on rich knowledge of self and psychological processes. For example, recent studies on age-related differences on everyday problem solving tasks found that older adults can solve problems as effectively, or even, better than younger adults do. Especially in emotionally salient and interpersonal problems, older adults are more effective than is true of young, evidencing a greater flexibility and adaptability than do younger ones.

Finally, a large body of work suggests that apparent decrements in later life often reflect the lack of relevance for older individuals. In contrast, if tasks are constructed so as to be interesting to the elderly, their performance typically increases. Such findings suggest that age differences can be eliminated when information to-be-remembered is relevant to older adults.

Conclusion

In this article, we address the mix of positive and negative changes in emotion regulation observed with aging. It proposes that this diversity of findings can be explained and systematized by a theory that outlines the coevolution in individual development of cognitive structures and emotion regulation capacities in such a way that individuals develop more effective means of maintaining equilibrium. On this formulation, the growth of cognitive structures and their integration with emotional systems in early development is related to an expansion of the range over which individuals can maintain equilibrium, as well as a raising of the thresholds of tension individuals can manage. The resulting cognitive-emotional schemas or representations themselves can become highly automated or crystallized, providing individuals with available means of regulation that although at first dependent on the expenditure of effort, eventually come to function in a relatively effortless way.

In contrast to development from childhood to middle adulthood, later life appears to bring a cessation of this expansive developmental process as the capacity for high tension and effortful performances decreases as a result of the decline of fluid processes of cognition. As a result, aging is typically associated with a lowering of tension thresholds and a restriction of the range of equilibrium. However, these restrictions may be limiting only in cases where individuals cannot fall back on already well-developed representational systems, instead needing to expend high levels of tension, stress, and effort.

By placing cognitive-emotional processes in the context of equilibrium regulation, the proposed theory provides, we believe, a coherent framework to discuss cognitive-emotional processes from a psychological and biological perspective alike. The notion of lowered equilibrium thresholds with aging already is commonplace in the medical and biological field, such as cardiac stress tests or recommendations for physical exercise regimens. By applying a similar conception to the field of emotion regulation, the current theory provides a linkage of the cognitive functions of emotion regulation to mechanisms of arousal and activation.

Abstract

The purpose is to show the dynamic of change and stability in the development of identity and self during adolescence. We present some basic differences between the development of self-perceptions and the development of identity according to Erikson's psychosocial formulation. The change and stability dynamics of identity development is subjected to critique from the perspective of the status paradigm as well as more recent theoretical models. The key role of the cultural context's inevitable influence on the development of identity and self-perceptions through the production of relevant cultural variations is also analyzed.

Introduction

Adolescence is usually defined as a 'developmental transition,' because in the broader context of the life cycle it represents, a period of change, growth, and transformation from childhood immaturity to the physical, psychosocial, and sexual maturity of adulthood. All the challenges in the form of 'developmental tasks' that the teenager must face are synthesized in the establishment of a sense of identity or self at the end of this period. Today, the period of time needed for this process must be considered as lasting up to the years of so-called 'emerging adulthood,' at least for a substantial and ever larger number of youngsters in many societies around the world. While major changes in self-perception also occur during childhood, such a degree of self-awareness and capacity for self-reflection is reached for the first time in adolescence.

It is important to grasp the intrinsically psychosocial and transactional nature of identity development, as revealed by Erikson (1968). Identity is located at the major crossroads of individual and social processes: it bestows, on the one hand, individuality – the person experiences himself or herself as a unique person; and on the other, a sense of belonging linked to the social context and recognized by the subject. Adolescent identity is the result of mutual recognition between the adolescent and society: the teenager forges an identity, but at the same time society identifies the teenager. The formation of identity thus involves a continuous interaction between the person and the context. Multiple levels of analysis and different theoretical approaches to the study of the self and identity in adolescence have led to diverse modifications to this basic premise, which means that both concepts stand in need of some clarification.

Definitional Issues

The development of self and identity is first and foremost a complex, multifaceted process that combines conscious and unconscious elements. It can be considered as a series of interrelated developments covering all the changes in the way, adolescents see themselves in relation to the others and to their sociocultural context. As these changes have been addressed by both psychological and sociological research, there has been great diversity in the definitions given to the basic concepts at stake. The most persistent distinction is between 'identity' and the related term of 'self.' Although some consider it artificial, this distinction is generally assumed to be valid and to need careful clarification. Beyond this continuing lack of agreement, it is, however, possible to recognize some points of convergence in the current theoretical debate that help to frame the development of identity in adolescence.

Firstly, there is an emphasis on the careful description of the phenomena studied, whether they be specific aspects of adolescents' own beliefs and evaluations of themselves, of their particular configurations of roles, identities, and values, or of the selection and processing of self-relevant information. Likewise, it would be clearer to refer to each term as a separate construct by means of the prefix 'self' until we know how they are related. In order to perform this task of clarification, it would be helpful to differentiate between inclusive levels of self-organization combining the temporal dimension (employing different time scales) with other parameters such as the degree of internalization or reflexivity. This way, self-evaluations and self-perceptions, for instance, would be located on an intermediate time level and as part of a first-order reflexive process, while the concept of identity would be located on a longer timescale typical of long-term developmental processes and as part of a second-order reflexivity (Lichtwarck-Aschoff et al., 2008). Self-representations would thus be considered as components of the identity.

Secondly, different theoretical approaches recognize several levels at which identity and self can be defined and understood: the personal or individual level, the relational level, and the social or collective level. Personal identity refers to those aspects of self-definition at the individual level including goals, values, beliefs, and a whole set of associated self-representations and self-evaluations. Relational identity refers to the contents of identity present in 'face-to-face' interactions and that have been framed in a variety of social roles and positions (son, student, friend, etc.). It also covers the way adolescents define and interpret these roles. Collective identity refers to all the cognitive and affective aspects deriving from belonging to certain groups with which adolescents identify themselves and which place them within certain social

 http://dx.doi.org/10.1016/B978-0-08-097086-8.23028-6

categories such as ethnicity, nationality, or gender. Alongside these three generic levels, another two levels of undeniable psychosocial significance have been identified. On the one hand, at the most basic psychological level, there is the ego identity, which remains largely unconscious and whose essential characteristic is its provision of a more subjective sense of time–space continuity than that associated with the personality. Erikson gave great importance to the function of an ego structure in creating this experience of personal continuity. On this account, the ego identity would be responsible for testing, selecting, and integrating self-images, and its chief function would be the unconscious synthesis of impressions, emotions, memories, impulses, and actions. On the other hand, cultural identity is differentiated as an aspect of social identity, which refers specifically to those cultural groups to which the person belongs and, in the case of immigrants, to their heritage and receiving communities. Cultural identity may be seen as midway between personal identity and collective identity. It includes domains such as adopted cultural practices, emotional identifications with the original cultural group and the receiving society, and value orientations.

Finally, there is currently a clear awareness of the need for theoretical and empirical integration in the study of both contents and identity processes at their several levels. As Vignoles et al. put it (2011: p. 9), "irrespective of levels of content, any given aspect of identity can be viewed as defined by individual, relational, and collective processes: as the subjective understanding or experience of individuals, as an interpersonal construction, and as a sociocultural product." Details of these tendencies are set out in the next two sections, which concentrate on the two most important approaches to the study of self and identity in adolescence.

Development of Self-Perceptions and Self-Esteem in Adolescence

Self-psychology has traditionally focused on the Jamesian distinction between the self 'as active knower' (I-self) and the self as 'known' (Me-self), in a way that is comparable to Erikson's distinction between the ego and the self. Most of the literature on self-development in adolescence has focused on the second level of analysis, i.e., the Me-self as the object of one's knowledge. In this regard, most studies have centered on the perceptions and evaluations that the teenagers have about their 'self' and its association with indicators of psychosocial adjustment and mental health.

Moreover, there is growing recognition of the difficulty of separating the evaluative dimension (self-esteem) from the purely descriptive dimension (self-concept) in self-representations because most of them are linked to a particular assessment, which is inevitably more or less positive. The current trend is to differentiate between domain-specific and global components of self-perception. On this view, the self-concept is considered to be the domain-specific assessment of capabilities (in a descriptive and an evaluative sense), while self-esteem represents the general sense of self-worth as a person. Most models further assume that self-perceptions are multidimensional, hierarchical, and progressively differentiated with age. Due to its hierarchical nature, self-esteem as a general statement of self-worth is located at a higher level, with specific domains (cognitive, physical, or social) and subdomains located in the subordinate levels of the structure of self-perceptions. Self-esteem is the most important factor in psychological well-being, but it is influenced by the self-assessments made in the subordinate domains (e.g., academic performance or physical appearance). Finally, most theoretical models agree that the self-concept is formed during childhood, when domain-specific differentiations are already under way, and undergoes faster differentiation and achieves potential consolidation during adolescence. This last point deserves more attention because of the intensity and variability of these changes.

Cognitive maturation in adolescence does not mean that the teenager quickly develops a consistent theory of the self. What happens instead is that the self-concepts undergo a series of progressive changes in their content, structure, and organization throughout this period. Therefore, the achievement of this more consistent and internally stable scheme of the self only starts to take place in early adulthood. As for the contents that teenagers often include in their self-representations, there are changes related to the vital areas, which are most important in each developmental stage. In early adolescence (12–14 years of age), attributes, interpersonal feelings, and social skills that influence interactions with others or affect the social image become the most prominent. By middle adolescence (15–16 years of age), self-descriptions contain a greater variety of psychological traits and a number of attributes reflecting increasingly personalized beliefs, values, and moral ideas. In late adolescence (17–19 years of age), these materials are typically added to concerns about 'future selves' and to the plans put in place to achieve them.

As for structure, the direction of these changes points in two directions: self-concepts become more differentiated at the same time as there is a growing tendency toward integrating these multiple self-representations into larger and more consistent units. In a developmental sense, differentiation is predominant until middle adolescence, with integration taking over in the late adolescence. The path to adulthood requires the integration of these multiple self-perceptions into a coherent, unified theory of the self. This path starts with the preparation by the teenager of some early abstractions that integrate concrete descriptions of the self (Harter, 2012). It is only in late adolescence when the capacity to build higher-order abstractions permits the integration of isolated and contradictory abstractions into a more consistent self-concept (e.g., 'depressive' and 'cheerful' do not enter into conflict with each other because they are part of being someone 'with mood changes').

Research has addressed the issue of the pattern of change in self-esteem across adolescence and whether these changes confirm the view of adolescent development as an intense period of 'storm and stress.' In general, self-esteem during adolescence tends to remain stable with age. However, there is a transitional period during early adolescence where the positive feelings about oneself decrease significantly between 12 and 13 years of age, in both boys and girls self-esteem reaches its lowest levels due to the psychosocial impact of major pubertal change. From here there is a progressive recovery until late adolescence, in a U-shaped fashion.

Some studies have shown that if stability is analyzed only in terms of average differences, qualitatively different developmental paths in self-esteem could be concealed. More flexible person-centered methodologies are required to address this important issue. In a recent study, Morin et al. (2013) used growth mixture analysis to identify four trajectories in adolescence based on global self-esteem levels and fluctuations: (1) *moderate* (56.2% of the sample, with moderate levels of self-esteem that remained stable over the course of the study), (2) *low* (19.3%, low and unstable levels of self-esteem), (3) *increasing* (11%, increasing levels of self-esteem and stability), and (4) *elevated* (13.5%, elevated levels of self-esteem and stability). As previous research has shown, each path in self-esteem differed in its pattern of correlations with other variables, in this case, those relating to individual perceptions of various aspects of school life. Their research also illustrates the existence of a group (around 20% of the sample) manifesting the most negative developmental pattern associated with the 'storm and stress' view of adolescence. The association between the levels and stability of self-esteem is another outstanding result, consistent with the self-equilibrium hypothesis. These researchers state in their conclusions, "tend to co-occur so that students with high global self-esteem show a greater level of longitudinal equilibrium in their levels of global self-esteem whereas students with low global self-esteem present an apparently highly reactive, unstable, longitudinal profile" (Morin et al., 2013: p. 19). Adolescents at greater psychosocial risk (low trajectory) are those whose self-esteem is more reactive and sensitive to changes in their context and who may thus benefit particularly from interventions designed to improve their self-perception.

Much attention has been paid to self-perceptions as a factor associated with psychological adjustment throughout the life cycle. For example, having a high self-concept in different domains and a sense of self-worth has been considered to protect against poor mental health (depression and anxiety) as well as risk activities, and antisocial or delinquent behaviors. High self-perceptions have also been shown to be connected with higher levels of academic performance and adaptation. However, somewhat more controversy attaches to giving any precise definition to the character of this widely observed association. Clearly, self-perceptions are related temporarily in a reciprocal fashion to indicators of adjustment and psychological well-being, thereby functioning as both a predictor and an outcome of healthy development. In contrast, the attribution of a true causal role to self-esteem has come in for criticism. Many of the associations detected between the level of self-esteem and some adaptation indicators may be the effects of common causal factors impacting both self-esteem and these indicators. This might have overinflated the impact of self-perceptions on adolescent functioning. So what role should be given to them? Based on current evidence, it is, on the one hand, reasonable to consider global self-esteem as a good indicator of overall psychological well-being in adolescence, or alternatively, as a risk marker for future development, and self-perception in specific areas as reflecting a component of self-efficacy in each domain. On the other hand, while the average level of self-esteem has no explanatory power per se, it has been noted that the variability of self-esteem is more likely to be the factor that impinges most on to adaptation. Several studies conclude that adolescents who show more severe fluctuations in self-esteem (compared to those with greater stability in high or low self-esteem) are more likely to behave aggressively and to suffer mental health problems. The relative independence of these two aspects has not been proven one way or the other, so it remains an open question for future research.

Development of Personal Identity in Adolescence

Erik Erikson initiated a tradition in the study of the concept of personal identity. His interest in this topic was clearly stated in his early work on World War II veterans, men who "did not know any more who they were" and therefore provided evidence of a "distinct loss of ego identity." As Erikson (1968: p. 67) observed clinically, "the sense of sameness and continuity and the belief in one's social role were gone." This was the first time in his career that he formulated the assumption of the importance of a sense of identity for a healthy person. For Erikson, adolescence was only completed when the individual could subordinate his childhood identifications to the choices and decisions he had to transform into meaningful commitments, which also needed confirmation by a significant social community. Although it was during adolescence that the task of creating a sense of identity attained its greatest ascendancy, according to Erikson every crisis showed elements of this identity formation.

The work of James Marcia marked the start of numerous critiques of the identity status paradigm, all with their origin in attempts to falsify Erikson's propositions in Ego Psychoanalytic Theory (Kroger and Marcia, 2011). Marcia's primary task was to determine what observable referents were available that might point to the presence of an identity structure. As no one can observe an identity, these observable referents were important if any empirical research was to be possible.

Marcia chose two dimensions, exploration (originally called crisis) and a commitment to empirically document the identity process. Exploration referred to some period of rethinking and trying out various roles and life plans. Commitment referred to making a choice to adhere to one's values, goals or beliefs in a given life domain and the ability to make future projections with regard to this choice. The four identity statuses based on the criteria of exploration and commitment were as follows: Identity achievement – when a person has undergone exploration and is currently committed; Moratorium – when a person is in an exploratory period and therefore bereft of commitments; Foreclosure – when the person has not explored but is committed to one or more choices; and Identity diffusion – when the person is characterized by a lack of both exploration and commitment.

Early research with identity status focused primarily on individual personality and cognitive and relational differences across the four different status positions. Although the initial method for obtaining evidence of these statuses was the Identity Status Interview, whose focus was deliberately qualitative and developmental, the most subsequent research has used questionnaires. By means of questionnaires such as the Objective Measure of Ego Identity Status, the four statuses have been correlated extensively with different personality variables

such as self-esteem, anxiety, moral reasoning, and ego development (Kroger and Marcia, 2011) with a view to finding differences between the statuses that would imply changes in the underlying identity structure.

Achievement has been associated with balanced thinking, mature interpersonal relationships, and thoughtful consideration of potential life options. Individuals with foreclosure status are inflexible and defensive. They have been associated with high self-worth but also with rigidity, closed-mindedness, and authoritarianism. Moratorium is the identity status with the lowest level of well-being and characterizes young people in an identity crisis. In many ways, they resemble achievement individuals in their cognitive complexity and higher levels of moral reasoning, yet they also demonstrate greater openness to experience. But this status has a dual trait so that an individual in moratorium may be an explorer but also suffer paralysis. Diffusion is less homogeneous as a group, but individuals with this status share an inability to make definite commitments and decline to explore options. Some diffusion individuals may go through life in a carefree, uninvolved way, while others manifest a severe psychopathology and great loneliness.

It has been recognized that the main drawback of this quantitative approach based on the use of questionnaires was the creation of a 'static' sociological conception of identity, which was more interested in classifying individuals into categories (the statuses) than in examining the complex psychodynamic that Erikson had initially described. In view of this major drawback, at the beginning of the last decade, instead of answering calls to abandon identity status theory, some models were developed in order to extend or expand its original formulation. What emerged from these extensions of the theory were such original contributions as the works of Luyckx et al. (2011) and of Crocetti et al. (2008).

Luyckx and colleagues model subdivided exploration and commitment into two different processes. Exploration included exploration in breadth and exploration in depth. In the same way, commitment differentiated between commitment making and identification with commitment. Both exploration in breadth and commitment making are equivalent to Marcia's original dimensions. Exploration in breadth refers to the gathering of information about several identity alternatives (values, roles, careers, relationships, ideologies, etc.), while commitment making refers to establishing strong choices in different identity domains as a consequence of prior exploration in breadth. What is new is the evaluation of those commitments, which were enacted previously. This commitment evaluation phase begins with exploration in depth, that is to say, a closer examination of those commitments after choosing them. Identification with commitment follows after a period of exploration in depth in order to integrate one's commitments into one's sense of self; in other words, identification with commitment is a measure of the degree of fit or agreement between those commitments and one's own wishes and personal standards. The interaction of the four processes is far from being simply linear. Not only may exploration in depth influence identification with commitment, but also a lack of identification with commitment may influence the need for a prolonged exploration in depth of those commitments or a renewed exploration in breadth of alternatives (Luyckx et al., 2011).

Crocetti et al. (2008) provide a second new extended model of identity. In their studies, identity is operationalized as a three-factor model with interplay among commitment, in-depth exploration (the extent to which individuals reflect on their commitments), and reconsideration of commitment (comparison of present commitments with alternative ones when the previous ones are no longer satisfactory enough). Individuals begin the process in early adolescence with a set of commitments in at least the ideological and interpersonal domains. These commitments are explored through reconsideration of commitments and through in-depth exploration. Reconsideration compares present commitments to alternative ones and includes decisions about whether to change them or not. In-depth exploration is a continuous monitoring of present commitments with the function of making them more consciously and maintaining them. In this model, commitment is not differentiated.

These newer distinctions of exploration and commitment offer interesting insights into the process of exploration. Luyckx et al. (2011) introduced the concept of 'ruminative exploration' to explain the paradoxical yet common association of exploration with both distress and openness to new experiences. Ruminative exploration refers to an obsessive concern about making the 'correct' choice, with the result that the person remains 'stuck' in the exploration process. This recurrent finding was in fact due to the merging of multiple exploration processes, which had not been distinguished in the original identity status theory. According to said authors, exploration in breadth and exploration in depth are associated with the positive side of exploring new alternatives, ruminative exploration with the negative side of distress.

The introduction of new distinctions in the processes of exploration and commitment has understandably provided some additional variants in the original statuses (see **Table 1**). From the combination of the three factors proposed by Crocetti et al. (2008), five identity statuses emerge: achievement, early closure, moratorium, searching moratorium, and diffusion. From the combination of exploration in breadth, exploration in depth, commitment making, and identification with commitment, cluster analysis identified the following statuses (Luyckx et al., 2011): an achievement cluster, another of foreclosure, two variants of moratorium (adaptive and arrested), and two of diffusion (carefree and diffused).

Another recent contribution of these two extended models has been to answer the age-old question of whether any developmental sequence underlies the identity statuses. Recent meta-analysis studies have tried to find out whether identity develops progressively and whether identity statuses can be ordered on a developmental continuum. Kroger and Marcia (2011) discussed a review of 124 longitudinal or cross-sectional studies performed before 2005, with adolescents (13–19 years of age) and young adults (20–36 years of age). Their conclusion was that the data generally supports a developmental process of identity formation. This means that there are more progressive than regressive developmental movements over time (D → F, D → M, D → A, F → M, F → A, M → A). Meeus (2011) concluded with respect to progression and stability that studies generally show a developmental progress in personal identity during adolescence. But, in addition to progress, many cases of stability have also been

Table 1 Identity status classification as per Crocetti–Meeus (shaded) and Luyckx models

	Processes					
Statuses	*Exploration in breadth*	*Commitment making*	*Reconsideration of commitment*	*Exploration in depth*	*Identification with commitment*	*Ruminative process*
Achievement		High	Low	High		
Achievement	High	High		High	High	Low
Early closure		Moderate	Low	Low		
Foreclosure	Low	High		Low	Moderate	Low
Searching moratorium		High	High	High		
Moratorium		Low	High	Low		
Moratorium (adaptive)	High	Low		High	Low	Low
Moratorium (arrested)	High	Low		High	Low	High
Carefree diffusion	Low	Low		Low	Low	Low
Diffused diffusion	Low	Low		Low	Low	High
Diffusion		Low	Low	Low		

reported since many adolescents and adults do not change their identity status, such stability being more common in adulthood than in adolescence. Stabilities were more frequent in the high commitment statuses than in the diffusion and moratorium statuses. It can therefore be concluded that adolescents may follow two distinct paths on the identity status continuum: D → F → A or D → M → C → A.

Recently, Meeus et al. (2012) have confirmed that it is better to conceptualize achievement, moratorium, early closure, and diffusion as trajectories rather than statuses. On this account, every status would be an example of an "over time solution of the identity puzzle" (p. 1017). By combining the three dimensions of commitment, exploration in depth and reconsideration of commitment they found the following trajectories: 15.8% of the respondents were classified within a trajectory of achievement, 39.6% within an early closure trajectory. A smaller number of respondents, mostly early-to-middle adolescents, were classified in the trajectory of searching moratorium. 20.5% of the respondents were in the moratorium trajectory. In contrast to searching moratorium, the moratorium trajectory describes participants without strong commitments, which have not been processed actively. In addition, they manifest a high level of depressive symptoms. Finally, 20.7% of respondents were in the diffusion trajectory. These trajectories are evidence of the richness and usefulness of Marcia's original work on status. But in this case, statuses are understood as long and stable trajectories instead of a path of statuses that must be crossed.

Cultural Context and the Development of Self and Identity

Although Erikson conceptualized identity as the interplay between a person and his or her social or cultural context, the focus of psychological research has traditionally been on the individual, leaving aside the influence of the cultural context. Ethnicity, as an example of the cultural influence, is one of the barriers, which can limit or facilitate the construction of a sense of identity. Although initially introduced as just another domain of identity status research, issues arising from ethnic identity led to a questioning of the assumption that the identity status model was valid for adolescents and emerging adults who were not white, Westerners, or middle-class. Phinney defined ethnic identity as a self-constructed internalization of the meaning and implications of a person's group membership based on that person's attitudes and feelings toward his or her cultural background, ethnic heritage, and racial phenotype. Compared with identity statuses, ethnic identity involves choice limitations in the sense that one cannot choose one's heritage. As Phinney and Baldelomar (2011: p. 163) put it, culture "permeates the process of identity formation not just at a macro level but at every level of analysis. Culture is not at the periphery of identity formation but at its center." From this all-encompassing idea of culture, they regard identity to be relational to the extent that one's identity serves to distinguish oneself from others and to link oneself with others. Identity is therefore situated within a cultural context, which includes the range of options available to individuals.

Phinney and Baldelomar go on to propose the cross-cultural identity status model (see **Figure 1**). This model extends the original status model by including the sort of cultural orientation, which frames the identity work. For them, Marcia's status model is valid only for an individualistic culture promoting choice, individualization, and self-expression. Consequently, an interdependent or collective culture should also be included, which promotes tradition, conformity, and replication. This culture would favor narrow exploration in order to facilitate the achievement of an available identity from authority figures. In this line, on the basis of the work of Greenfield et al. (2003), they propose two different cultural pathways of development, which frame the process of identity formation and its outcomes.

An interdependent pathway of development, which whittles down exploration could lead normatively to an interdependent identity achievement, adapted to this cultural frame; an independent pathway of development could lead to an independent identity achievement characterized by a wide-ranging process of exploration. That said, someone who explored widely in an interdependent culture (to give just one example of a countercultural process) would also end up with an achievement identity. Someone who did not explore in an independent culture (another example of a countercultural

Figure 1 Sequence of identity statuses by cultural pathways of development. Phinney, J.S., Baldelomar, O.A., 2011. Identity development in multiple cultural contexts. In: Jensen, L.A. (Ed.), Bridging Cultural and Developmental Psychology: New Syntheses in Theory, Research and Policy. Oxford University Press, New York, p. 168.

process) would end up with a foreclosed identity status. It should be noted that foreclosure status would not be included in an interdependent pathway of development, in so far as adopting and internalizing the values and models proposed by the community is the ideal trajectory for successful adaptation.

Recent research conducted in different countries around the world provides interesting examples of these two cultural pathways (Schwartz, 2012). As far as independent cultural orientation is concerned, in Europe, there have been studies in Belgium, the Netherlands, Germany, and Italy. All emphasize the importance of individualized exploration and self-expression processes. Nevertheless, they present different findings with respect to the resources provided by political and economic institutions to help in supporting the younger generation in their task of exploration. The cases of Japan and Sweden show a combination of independent and interdependent cultural orientations. Research based on identity status in Japan has been revised from the optic of a culture, which stresses interdependence and its values of conformity, tradition, and replication. However, from 1990 individualistic values such as the importance of being creative and getting achievements as promoted in education and the mass media have given rise to a new configuration termed 'individualistic collectivism,' which incorporates a strain of individualism and autonomy into Japanese identity formation. For its part, and like Germany and the Netherlands, Sweden stands out for of its social structural support policies, which has generated an interesting model with a marked emphasis on tolerance, equality of outcomes, and social welfare, despite a traditionally individualistic perspective. Thanks to this, Swedish youngsters can postpone their transition to adulthood and, with backup from the social system, are able to explore openly more options.

The formal consideration of one's culture has provided interesting insights into our understanding of how our identity is formed in interplay with its immediate context. Far from considering identity as only the product of individual processes, current research demonstrates the importance of relational, social, economic, political, and historical factors. The inclusion of research from around the world fills out the conventional picture drawn by studies in North America and Europe. This is even more important when we take into account how issues of cultural diversity are becoming more common and crucial all around the world. In a globalizing world, knowing just one culture, and its implied independent or interdependent pathways of identity formation, is going to be almost impossible for today's adolescents and emerging adults. As a result of globalization and its processes of mass

immigration, all individuals, members of majority or minority groups alike, must deal with themselves as cultural beings. In today's world, developing a cultural identity entails the integration of multiple cultures.

Conclusions

The convergence between theoretical and empirical approaches to the development of self and identity in adolescence is now the trend that is shaping the future in this area of study. Research into adolescence has benefited from the awareness of the complexity of such questions as what identity means and how identity processes operate. Two broad lines of work reflect this integration. One line seeks to connect together developmentally various dimensions of personal identity and self-concept as components of a dynamic self-system. The study of the implications of these connections for the psychosocial functioning and the psychological health of the adolescents has also intensified. Longitudinal studies combining a focus on longer time periods and short-term contextual fluctuations are helping to clarify the dynamics between change and stability in the various elements and levels of identity between early adolescence and emerging adulthood. In adolescence, active wide-ranging exploration and the reduction of uncertainty through the maintenance of tentative commitments contribute to a clear self-concept, i.e., to the configuration of a consistent, stable self-concept, and high self-esteem. Self-concept clarity in turn decreases the likelihood of reconsidering commitments and amounts to protection against the internalizing problems of anxiety and depression. However, in emerging adulthood, more importance is attached to an identification with commitments when psychosocial well-being and the increase of self-esteem are at stake. Therefore, normative trends in the consolidation of self-concept in early and middle adolescence provide the foundations for social and personal identities that are ultimately expressed as the resolution of the task of identity. Thus, a form of personal agency might be postulated, which was involved in identity formation during late adolescence and emerging adulthood but did not occur in the earliest stages of the development of the self-concept and of the adoption of the first customized commitments.

On the other hand, there is a growing interest in clarifying the interrelationships between personal identity and cultural identity in the framework of the effects of globalization on adolescent development. Personal identity seems to mediate the relationship between cultural identity and psychosocial adjustment; therefore, it is essential to analyze the ways in which cultural processes affect the setting of goals, values, and beliefs characteristic of personal identity. The application of the distinction of cultural orientations (independent or interdependent) to both the configuration of a self-schema and to the way identity commitments are formed and reviewed will remain fruitful. It is clear that in some Western cultural contexts, with broad possibilities of choice in most domains, the adoption of commitments after an exploration period seems to be the most adaptive means for developing identity. However, the ways in which identity develops in culturally interdependent environments where exploration, time–space continuity of the self and personal agency are secondary are not well understood. The notions of 'wide' and 'narrow' exploration applied to different domains of self-concept and identity contained in the trans-cultural status model are suggestive. However, they are still insufficient, especially when it comes to accounting for the development of personal identity in situations of rapid cultural change as a result of migration or globalization, and all that implies for the negotiation of the multiple cultural identity options available.

Self in Culture: Early Development

Vasudevi Reddy, University of Portsmouth, Portsmouth, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Self and culture are both fluid processes. I focus on three aspects of self: the body, the awareness of self, and the regulation of behavior. In each of these aspects, the self can be seen to be open in relation and thus varying with cultural and situational influences. From very early in infancy, we can see cultural differences in motor skills, types of self-awareness, and difference of regulation of infant behavior. The development of selfhood is a dialogical, participatory, and thus a fundamentally cultural process.

> … the contents of our 'inner' lives are not so much 'inside' us as individuals, as 'in' our living of our lives. (Shotter, 1997)

Self and culture are arguably two of the three most slippery notions in the Social and Behavioral Sciences (the third, one could argue, is mind). The self cannot be contained inside the skin just as culture cannot be conceived of as outside it (Shweder, 1999). Both are fluid and continually developing. The self can best be understood as a relational entity, and thus, to understand the emergence of selfhood we need to understand its openness in relations of different kinds. In this article, I look at this openness within relation of three aspects of selfhood – the body, the awareness of self, and the regulation of self.

The Body

Cultures vary in the 'body techniques' they instill in their members (Mauss, 1979). These cultural habits of the body are not trivial in terms of selfhood. Our posture at a given moment reflects even trivial recent experiences; brief verbal priming such as the mention of old age, for instance, slows down the walking speed and posture of experimental subjects in laboratories (Bargh et al., 1996). And our posture can lead to different kinds of abilities and experiences; sitting with a confident posture (back erect and chest out) leads to greater confidence in our thinking than sitting with a doubtful posture (slouched forward and back curved, Brinol et al., 2009); and having our hands tied behind our backs impairs our ability to judge others' reaching ability (Ambrosini et al., 2012). Specific experience affects not only the way we move our bodies, but also the sounds we make with it in early infancy (Wermke, this volume) and the very experience of our body as our own. The rubber hand illusion, the whole body illusion, and enfacement illusions all show that if there is enough confounding of multisensory information we can be fooled into thinking that another body is our own, even if briefly and partially. This remarkable plasticity of body experience appears to be evident even in newborns (Filipetti et al., 2013).

Esther Thelen (2000) identified motor development as the foundation and the future of developmental psychology because motor development in this, the age of embodiment, is "not just motor anymore" (p. 394). Using Bernstein's revolutionary way of thinking about motor control not as something that comes only from the 'inside' but as something that lies in local factors such as joints, muscles, and the constraints and affordances of specific environment, we can see how situations and cultural invitations to move and to act require that children must learn, anew in each situation, the biodynamics of their bodies and the changing forces accompanying and producing each movement.

Motor development in infancy differs dramatically across cultures (Keller, 2002; see Formega and Kayenne, this volume). From the mid-twentieth century we know that African infants show motor precocity in a range of actions. This precocity appears to be cultural rather than genetic. Ugandan infants, for instance, are more advanced, especially in the first year of life, than American infants, regardless of race. The African advantage also seems to disappear when the children grow up in Western environments. Differences in motor skill appear to be specific to local cultural encouragement or discouragement of specific motor practice: Brazilian infants sit and grasp later than American infants, arguably because their mothers are more protective about physical risks in allowing their infants to sit and stand. Cultural variations in age of onset and proficiency in motor skills can come from different sources, from variations in practices of handling infants (which are largely logistic and pragmatic in specific environments) from ethnotheories about the stimulation of general motor skills, and from practices for training for specific skills.

Variations in maternal practices in handling infants – even newborns – vary, and these may enhance specific muscular development. Uganda mothers, for example, tend to pick up infants around the chest without head or back support, or lift by one of the shoulders or even lower newborns into cribs in this way. Holding infants out when the infant begins to urinate, or holding them in a squatting position to defecate may also help to strengthen muscles in the legs and back. Informal routines such as keeping babies lying down or sitting up also vary across cultures. French infants, for instance, spend 50–60% of their day lying down, while infants in Uganda, Botswana, and Mali spend 40–90% of their day sitting or standing, or being carried. Restricted time in a prone position in back-sleepers (the most common practice in the United Kingdom at the moment) is linked with later onset ages for crawling and related skills that require the use of upper trunk and arms. Similarly, methods of carrying and transporting

infants vary enormously between cultures and afford the infant very different opportunities to explore their environments and give them different postural challenges to cope with. When mothers carry infants on their backs rather than in their arms, the infant requires better head control to compensate for the mother's movements, has the advantage of more practice at sitting (on the back) and can reach and grasp more objects with their arms. Such practice at frequent postural adjustment and opportunities for manual exploration may result in accelerated reaching (e.g., in the !Kung) and sitting (Adolph et al., 2012).

In many cultures, there are accepted practices – and different ethnotheories – for stimulating general motor development. Formal baby massage and stretching are common in many cultures in Africa, the Caribbean, and India and have often been shown to accelerate developmental progress (Adolph et al., 2012; Keller et al., 2002). Formal training of infant motor skills is not something that is common or even encouraged in Europe and North America. And yet, the specific effects of such training are clear; infant reaching skills can be accelerated, and infant crawling can be accelerated (down to five and a half months) by mothers who teach these specific skills. Jamaican mothers in the United Kingdom who continue the massage and formal training of their native culture have infants with better head control at 1 month (also compared to English infants), who sit and walk earlier than the Jamaican infants of mothers who do not continue the massage and formal training (Hopkins and Westra, 1988, 1990). The effects of training generally seem to be specific; the frequency of formal exercise in sitting and walking predict the age of sitting and walking, but not the age of crawling. Mistakenly believing that it is better not to help with the acquisition of motor skills can lead to a delay in several motor milestones and reflects an odd assumption of the closed-ness to cultural influences of motor development.

Does advancing the age of onset or increasing the proficiency of motor skills matter for selfhood? There is considerable evidence that new locomotor skills (such as crawling or walking) transform the infant's relation to the world, opening up new and different opportunities for action and discovery and allowing different sociocognitive skills (Campos et al., 2000). Cultural variations of practice as well as expectation in terms of infant mobility thus open up new avenues for cultural differences in social cognition. What others do with our bodies in infancy affects what we do with our bodies, which in turn makes a difference to how we think about and perceive ourselves in the world.

Awareness of Self

Being is often influenced by the awareness of being. Do early experiences also influence the extent to which and more importantly, the way in which, we are aware of ourselves? The reflexive awareness of self has in the past been lauded for being the great achievement of *Homo sapiens*; although this claim to exclusivity is less strongly made nowadays, the complexity and impact of human self-consciousness on human lives is beyond doubt. This section will focus on two aspects of self-awareness that might be open to cultural variations: the way in which infants reach an awareness of the I, and the way in which they experience self-conscious affects.

Detecting the 'I'

The ability to distinguish self from nonself is an early one and very likely to emerge from the ability for agentic movement. Neonates can tell the difference between their own hand brushing their cheek and another person's hand stroking their cheek, showing more rooting responses to the latter than to the former (Rochat and Hespos, 1997). Even fetuses appear to distinguish between their own body, that of their twin, and the uterine wall; upper limb movements toward the twin are of longer duration and show longer periods of deceleration than movements toward their own body (unless toward their own face) or toward the uterine wall (Castiello et al., 2010).

However, this basic ability to detect one's own movements is only half the story in the development of an awareness of the 'I' and the ability to act and do things; the other half is how the world responds, contingently, to these movements, creating a sense of successful agency as well as the sense of a responsive world. One month-old infants detect and like to explore, perfect contingencies (the kinesthetic-perceptual match between their own moving bodies and a live video of their bodies), increasing the movements of the seen rather than unseen arm even when the arm has additional weights hung on it to make it more difficult to move (Van der Meer et al., 1995).

Contingent responses from the world are clearly pleasurable, leading to smiling and experimentation in infants (Watson, 1972) and activating the reward centers of the brain in adults (Schilbach et al., 2010). The most frequent (and possibly the most pleasurable) experiences of contingency that infants experience in the early months are of course, from other people. If these vary, as they must, between cultural situations, infant propensities for acting and for exploring actions must vary too. Violations of contingent responsiveness by others are detected very early in life (Murray and Trevarthen, 1985; Nadel et al., 1999; Markova and Legerstee, 2006) and may affect patterns of attachment and relationships as well as how infants perceive and recognize themselves (Gergely, 2004). Cultural variations in the degree and style of contingent responses, which infants receive appear to vary along the dimension of independence–interdependence, with 'independent' cultures seeing contingent responses as recognition and encouragement of infants' agency, uniqueness, and expressiveness. German mothers (from an independent cultural orientation) appear to show more contingent responsiveness, while Greek mothers (more family oriented) show more warmth to their 3-month-olds; similarly, rural Cameroonian mothers (from a more interdependent orientation) show less contingent responsiveness than do German mothers (Keller et al., 2005).

At least within a Western cultural environment, receiving more contingent responses to their smiles from their mothers tends to encourage infants to make more social bids (attempts to regain engagement) during the still face procedure (McQuaid et al., 2009). However, given that infants learn very early to prefer the degree of contingent responsiveness that they are used to (Bigelow, 1998) the generalizability of this finding to other cultures cannot be

assumed. Cultural differences in forms of contingent response appear to have knock-on effects for the way in which objective self-awareness – that is, the recognition of the self as a 'me' – develops, with infants who receive greater contingent responsiveness from their mothers showing earlier mirror self-recognition (Keller et al., 2004). These findings have to be treated with some caution, since infant mirror experience also varies between cultures and rapidly influences mirror self-recognition. Although in their main experiment Cameroonian infants performed less well than German infants in mirror self-recognition, at a follow-up test only 6 weeks after the first test, the Cameroonian Nso infant performance improved dramatically. The validity of the mirror self-recognition task has been challenged in several ways, most recently in a cross-cultural study of older toddlers, that touching the self in the mirror (taken as evidence of self-recognition) itself varies between cultures, with much fewer self-referential acts in Kenya and Fiji than in the United States, Canada, Peru, and Granada (Broesch et al., 2011).

Interestingly, it may not just be the fact of or the extent of contingent responsiveness that varies between cultures, but also its content. American mothers (more than French or Japanese mothers) tend to respond to infant overtures more by directing attention to things in the environment, and Japanese mothers tend to respond more (than American or French mothers) to social looking by the infants, and with more dyadic than extradyadic responses (Bornstein et al., 1992). Similarly, the modality of contingent responses varies between cultures. Kaertner et al. (2010) compared the proportion of visual and proximal maternal contingent responses in Nso and German families. Although at the start of the study at 4 and 6 weeks of age there were few differences between the groups, by 12 weeks of age the differences were pronounced. The German mothers significantly increased their visual contingent responses and decreased their proximal contingent responses. Thus, very different features of the self are acknowledged and affirmed in different cultural groups from extremely early in life, with the impact of the differences increasing with age.

Feeling Self-Conscious

One of the most salient ways in which we reveal self-awareness is through self-conscious affectivity – typically involving emotions such as pride, shame, embarrassment, guilt, and jealousy. Although we no longer characterize cultures as cultures of guilt and cultures of shame (Benedict, 1967), the meanings of these emotions for the self and for the action potentials from these emotions vary enormously. Shame and pride appear to carry very different connotations in different cultures. In East Asian cultures, shame appears to carry with it a recognition of the ability – and the need – to communicatively rectify the damage to interpersonal relations, whereas in Western cultures shame is more often seen as an individual failing with no option for action, as something that cannot be rectified, and thus can only be responded to by withdrawal and hiding. With such a difference in cultural framing, it is not surprising to find the daily practice of communal *hansei* or self-criticism in Japanese classrooms in sharp contrast with the American practice of encouraging children to report and focus on their worthy achievements (Miller et al., 1996). Similarly, adult Japanese respondents appear to prefer to report a situation of shame or humiliation over one of pride, a preference that would boggle most Anglo-American adults who prefer instead to hide it. Shame in East Asian cultures is "one way of showing social engagement" (p. 163), with options – or even a requirement – for public action and reparation (Mesquita and Karasawa, 2004). Consistent with its 'invisibility' in Western adulthood, the ontogenetic emergence of shame appears to be relatively late in Western cultures (Miake and Yamazaki, 1995). Pride, on the other hand, appears to be something that Anglo-American cultures are more comfortable with, with a well-known emphasis on remembering to praise children's achievements (Levine et al., 1980). This is consistent with the general encouragement at all ages to show off one's achievements rather than hide them in embarrassment or be self-effacing. That infants before the end of the first year are proficient in showing off (at least in the United Kingdom) is known (Reddy, 2005); whether there are differences between Anglo-American cultures and Asian or African cultures in terms of infant or child proclivity to show off is as yet unknown.

Shyness or bashfulness is another self-conscious affect that is generally seen as a problem in Anglo-American cultures (as juvenile, immature, and perhaps even socially problematic). In contrast, it is seen as attractive in India and in East Asia. A quick look at movie hoardings in India would yield an impression that attractiveness in young women is associated with demureness and smiling with sideways glances. Indeed, even in a work context, the term conveys different cultural values, implying a desirable quality in employment in India, as opposed to a distinctly worrying quality in the United States (Shweder, 2003). It has also been claimed that the Japanese kimono with its long sleeves particularly favors the revealing of smiling eyes without showing the smiling mouth – the classic sign of a coy smile. Infants do show positive shyness very early in life (Reddy, 2005) but we do not know as yet whether this affective expression – charming as it is in infants – is responded to differently in different cultures, nor whether its frequency differs. The suggestion that the reasons for self-conscious affects change with age, emerging in more interpersonal context early in infancy but in more triadic contexts later (Mesquita and Karasawa, 2004; Reddy, 2005), suggests an intriguing possibility that in more interdependent cultures there may be a longer continuation of the interpersonal contexts of shame, pride, and embarrassment. If this is the case, then our attempts to understand self-awareness must shift to the kinds of interactions and actions that prompt selves to feel self-conscious.

Regulating Behavior

The regulation of behavior is a problematic issue in psychology. On the one hand, the pervasive cultural value in most of Europe and America is for freedom from control by others. The early Freudian assumption of a tension between society and the individual is still a familiar one. On the other hand, given that the only way out of this tension is through some regulation of individual behavior, (Western) psychology

puts its trust in the need for self-regulation on the basis of internalized rules. The solution is culturally consistent; the individual still has the freedom to regulate himself or herself without direct pressure from others, with the internalized rules forming a depersonalized and more acceptable intrusion on freedom. The issue of self-regulation has thus become central in psychology, with other-regulation (regulation by others) seen as a developmentally early and temporary form of influence.

Within this framework, adult directives to children hold an ambivalent position. They could be seen to be limiting the child's ability to act on their own and curtailing rather than expanding the horizons of potential actions. The Piagetian–Vygotskyan debate about the role of the teacher is directly relevant here, seen either as the person who stops the child from making his or her own discoveries or as the person who opens doors through a scaffolding process to help the child make more discoveries. Studies adopt a dim (and ethnocentric) view of parents who issue 'too many' directives, simplistically equating it with intrusiveness, status orientedness, and insensitivity (Pine, 1992). Children's compliance with directives holds a similarly ambivalent position; while docility with immediate control is seen as not necessarily desirable, compliance with rules – an internalized and self-regulating compliance as it were – is seen as more mature.

However, there is considerable variation between cultures in attitudes toward both these things – direct regulation by others and compliance with such regulation (see also Kagitcibasi, this volume). Western psychology's value for the internal may have led to a relative ignorance of how adults do, in fact, engage in participatory regulation with their infants and children, with such regulation opening up richer developmental opportunities for infants and children (Rogoff, 2003; Kaertner et al., 2010). In interdependent cultures, adults appear to be more indulgent and warm, more regulating, and more 'connected' with their children in contrast with independent cultures (there is less known and less agreement about the direct effects of this on the children). Most findings about such cultural variations appear to fall within a great divide narrative and thus must be treated with some reservations (Raeff, 2006; Kagitcibasi, 2005).

Japanese teachers (in an immersion school in the United States as well as at a school in Japan) have been shown to use more direct forms of command (including the declarative command – e.g., 'you shall sit down') than their English counterparts who favor less direct forms and questions. The intimacy with the children that often accompanies the direct commands appears to make the directness inoffensive and appropriate (Falsgraf and Majors, 1995). Greater use of direct commands has also been found to characterize parents on 'welfare' in the United States as compared to middle-class parents (Hart and Risley, 1995). Iranian parents in the United States (in contrast to Anglo-American parents) use more directives to their preschool children in a goal-oriented activity, although this style is unrelated to sensitivity (Kermani and Brenner, 2000). Similarly, Chinese immigrant mothers use more attention-directing than attention-following styles with their infants (Vigil, 2002). Individual differences in collectivist attitudes within a culture (e.g., in Estonia) do not, however, appear to be linked to maternal directiveness, with greater collectivism linked instead to greater talkativeness with their children (Tulviste, 2001). Directiveness, however, is not a unitary phenomenon; it varies in degrees of supportiveness and in intrusiveness and even intrusive directives can have positive consequences, increasing infants' attention to toys and play (Masur et al., 2013).

In general, patterns of compliance in toddlers and children in more interdependent cultures also seem to imply a deeper commitment and cooperativeness in the children. In a study of Greek, Costa Rican, and Nso families (which could be seen as varying in that order from more independent to more interdependent orientations), Nso toddlers (18–20 months) showed greater rates of internal regulation (complying without reminders) than did the Costa Rican toddlers, with the Greek toddlers being the least likely to comply. The amount of close body contact at 3 months – highest in the Nso – was found to be the strongest predictor of later internal regulation (Keller et al., 2004). A similar differentiation between independent and interdependent cultures can be seen in a study showing that Chinese toddlers in Canada display more committed compliance than Canadian toddlers who show more situational compliance (Chen et al., 2003). One explanation of this is that the independence-encouraging Canadian mothers allow their infants to take risks and rely on their own monitoring and reminding functions to manage the child, while the Chinese mothers use warmth, contact, and connectedness expecting (and getting) cooperation in return from the child.

However, compliance and noncompliance may not follow the same pattern through childhood, and may not have the same meaning at all ages or in all groups. Reddy (1983), for instance, found that at 7 years children in India were less compliant than children in the United Kingdom. Although there were more frequent adult directives in India, Indian parents showed greater eventual acceptance of noncompliance than in the United Kingdom. Compliance in India was often a longer drawn out negotiation than in the UK families. It is not necessarily the case, therefore, that greater regulation by others leads to greater self-regulation. Greater efforts at regulation may also accompany greater indulgence and tolerance of noncompliance and maternal directiveness does not predict child compliance in either Japanese or American 5-year-olds (Abe and Izard, 1999). In a study of compliance at the earliest stages of its emergence, before the end of the first year, infants in India showed higher absolute frequencies of compliance with adult directives than infants in the United Kingdom, but showed no differences at all in proportions of compliance (Reddy et al., 2013).

Independence–interdependence and directiveness may be too blunt a set of instruments with which to understand selfhood and regulation in childhood. A closer look at the content of directives, especially early in infancy, might be more informative. Even between 6 and 12 months, infants in India more than in the United Kingdom, receive an impressive range of adult requests for participation in cultural activities (such as prayer and ritual actions) and for social reenactment of interpersonal gestures and expressions (such as 'show how granddad gets angry' or 'show how you cry,' Reddy et al., 2013). Infants are drawn into culture both in relation to specific skills and into the practice of participation and may benefit from this in the same

way as they benefit from being trained in motor skills. Directives can be dialogical opportunities as well as intrusions, their meaning varying across situations and cultures in a multitude of ways. Such dialogical opportunities open doors for development and posit the developing infant as a dialogical self (Bento et al., 2012) born in intersubjectivity (Trevarthen, 1993). The difference between self-regulation and other-regulation may be more apparent than real.

Conclusions

The openness of self to culture can be seen in diverse ways in which we connect with and move with the world. In this article, we have focused on three aspects of self – the body, awareness of the self, and regulation of the self – which are open to engagement with the world. The self cannot be seen as an independent entity bounded by the skin. Whether we are talking about the way we sit or walk or move, or the way we are aware of our ability to be and to act, or the way in which our behavior is regulated in everyday life, our selves are dialogical entities. They contain the cultural world, just as the cultural world contains and is itself changed by the participation of each of these selves.

Abstract

It is often asserted that the concept of the self emerges only in early modern times in connection with the concern for subjectivity that is taken to be characteristic of modernity. While it is true that the term 'self' as a noun, describing that which in a person is really and intrinsically this person, comes into use only from the seventeenth century onwards, what can be called the question of selfhood was not unfamiliar to earlier thinkers. This is, in its core, the question whether there is – and if so, what is – some unity, or at least continuity and coherence, of a human being over the life-course beyond their bodily constitution, beyond the unity of the body. Broadly, empirical traditions tended to doubt the existence of such unity. They could observe changes, even radical transformations, in the human mind. Transcendental traditions, in contrast, tended to argue that there had to be a unity of apperception, or of consciousness. In the intellectual space between these two positions, so to say, the issue could be addressed in ways that are more specific to the social and psychological sciences. Starting out from observations by Georg Simmel and George Herbert Mead on the formation of identities in social interaction, a sociology and social psychology of selfhood and identity has developed that could conceptualize variations of self-formation in different social contexts. Over the twentieth century, research on selfhood has developed in a broad semantic space in which aspects of the self are emphasized in highly various ways, connecting the concept of self to notions of modernity, of meaning, and of difference.

It is often asserted that the concept of the self emerges only in early modern times in connection with the concern for subjectivity that is taken to be characteristic of modernity. While it is true that the term 'self' as a noun, describing that which in a person is really and intrinsically this person, comes into use only from the seventeenth century onwards, what can be called the question of selfhood was not unfamiliar to earlier thinkers. This is, in its core, the question whether there is – and if so, what is – some unity, or at least continuity and coherence, of a human being over the life-course beyond their bodily constitution, beyond the unity of the body.

In the history of human thought, this question has been answered in a great variety of different ways. Broadly, empirical traditions tended to doubt the existence of such unity. They could observe changes, even radical transformations, in the human mind and had thus no ground to postulate any *a priori* unity. Transcendental traditions, in contrast, tended to argue that there had to be a unity of apperception, or of consciousness. Otherwise, not even the question of the self could be asked.

In the intellectual space between these two positions, so to say, the issue could be addressed in ways that are more specific to the social and psychological sciences. Then, the faculty of memory, for instance, could be seen as enabling a sense of continuous self to emerge. Human subjects have the ability to narrate their lives. Or, selves could be seen as formed in the interaction with others, that is, in the mirroring of an image of oneself through the responses to one's own words and actions by others. In moral philosophy, the existence of a continuous self was seen as a precondition for holding human beings accountable for their past deeds. Selfhood was thus linked to moral and political responsibility.

Selfhood in the Social Sciences

In these forms, the question of the self was already posed at the historical moment when the social sciences, by and large in the contemporary understanding of the term, arose towards the end of the eighteenth century. It is noteworthy, then, that the emerging social sciences rather reduced the range of ways of exploring selfhood across the nineteenth century. In some of their fields, like liberal political philosophy and political economy/economics, they postulated a rational self, able to make choices and to be responsible for her, or rather: his deeds. In other fields, in particular in the sociological way of reasoning, the orientations and behaviors of human beings were seen as determined by their social position. This opposition has become known as the one between an under- and an oversocialized conception of the human being (Wrong, 1961). More cautiously, the empirical and behavioral strands of social research restricted themselves to observing human behavior and refrained from making any assumptions about selfhood at all. Regularities emerged here only through the aggregation of observations.

All these approaches had in common, though, was that they aimed at regularizing and stabilizing human orientations and behavior. Whether human beings were under- or oversocialized or just happened to behave according to patterns, the broader question of selfhood, namely whether and how a sense of continuity and coherence in a human being forms, was rather neglected or answered *a priori* by theoretical postulate.

In this light, it seems appropriate to say that the social sciences have developed a serious interest in questions of human selfhood only late, systematically only in the early twentieth century. Furthermore, they have largely ignored ways of representing the human self that were proposed in other areas, in philosophy for instance, but maybe even more importantly in literature. Thus, issues such as individuality and subjectivity, the possible idiosyncrasy of a life-course and life-project, have long remained outside the focus of the social sciences, which have tended to look at the question from the perspective of a fully developed, stable, personal identity, rather than making the continuity and coherence of the self an issue open to investigation.

This focus can hardly be understood otherwise than through the perceived need to expect a political stability of the world on the basis of a presupposed coherence of human orientations and actions.

The ground for an interest in such broader issues was prepared outside of what is conventionally recognized as social science, namely by Friedrich Nietzsche, and later by Sigmund Freud. Nietzsche radically rejected the problems of moral and political philosophy and thus liberated the self from the impositions of the rules of the collective life. Freud located the drives toward a fuller realization of one's self in the human psyche and connected the history of civilization with the repression of such drives. Against such a 'Nietzschean-Freudian' background (Rorty, 1989), Georg Simmel and George Herbert Mead could observe the ways in which identities are formed in social interaction and conceptualize variations of self-formation in different social contexts. From then on, a sociology and social psychology of selfhood and identity has developed which no longer relies on presuppositions about some essence of human nature and is able to connect its findings to both child psychology and phenomenology. It emphasizes the socially constructed nature of selfhood, but remains capable, at least in principle, to analyze the specific social contexts of self-formation thus working towards a comparative-historical sociology of selfhood. This broadened debate on selfhood has created a semantic space in which aspects of the self are emphasized in various ways (Friese, 2001). This space can be described by connecting the concept of self to notions of modernity, of meaning, and of difference.

Selfhood and Modernity

The idea of human beings as autonomous subjects is often taken to be characteristic of modernity as an era, or at least for the self-understanding of modernity as an ethos (*see* Modernity: History of the Concept). Such a view entails a conception of the self as rather continuous and coherent, since only on such a basis is the choice of a path of action and a way of life as well as the acceptance of the responsibility for one's deeds conceivable. The concept of selfhood is here conditioned by the need to maintain a notion of human autonomy and agentiality as a basic tenet of what modernity is about, namely the possibility to shape the world by conscious human action. Such modernism, however, is not necessarily tied to the atomist and rationalist individualism of some versions of economic and political thought, most notably neoclassical economics and rational choice theory.

In the light of the twentieth century developments in sociology and (social) psychology, as mentioned above, the view that connects selfhood to modernity mostly – in all its more sophisticated forms – starts out from an assumption of constitutive sociality of the human being. Not absolute autonomy, but rather the conviction that human beings have to construct their self-identities can then be seen as characteristically modern (Hollis, 1985). Unlike the concept of the rational, autonomous self, this concept is open towards important qualifications in terms of the corporeality, situatedness, and possible nonteleological character of human action (Joas, 1996). Without having to presuppose the self-sustained individual of modernity, the aim is to demonstrate how autonomous selves develop through social interactions over certain phases of the life-course (Joas, 1998; Straub, 2001).

The commitment to autonomy and agentiality, characteristic of modernity, becomes visible rather in the fact that formation of self (or, of self-identity) is here understood as the forming and determining of the durably significant orientations in a life. It is related to the formation of a consciousness of one's own existence and thus biographically predominantly to the period of adolescence. Crises of identity occur accordingly during growing up; more precisely one should speak of life crises during the formation of one's identity. Self-identity once constituted is seen as basically stable further on. No necessary connection is presupposed between self-formation and individuality; theoretically, human beings may well form highly similar identities in great numbers. Since the very concept of identity is connected to continuity and coherence of self, however, stability is turned into a conceptual assumption.

Objections against such a conceptualization go in two different directions. On the one hand, this discourse, which often has its roots in (social) psychology, stands in a basic tension to any culturalist concept of identity, which emphasizes meaning. On the other hand, doubts about the presupposition of continuity and coherence of selfhood employ notions of difference and alterity that are not reducible to the idea that selves are formed by relating to others, by intersubjectivity.

Selfhood and Meaning

Some critics of the close connection between self-formation and modernity argue that every form of selfhood is dependent on the cultural resources that are at hand to the particular human being when giving shape to their important orientations in life. Human beings give meaning to their lives by interpreting their situations with the help of moral-cultural languages that precede their own existence and surround them. Cultural determinism is the strong version of such theorizing, mostly out of use nowadays, but many current social theories adopt a weaker version of this reasoning which indeed sustains the notion of the continuity and coherence of the self but sees this self as strongly embedded in cultural contexts.

Such a view of the self has its modern source in romanticism. Philosophically, it emerged as a response to the rationalist leanings of the Enlightenment, and politically, against the conceptions of abstract freedom in individualist liberalism. Unlike cultural determinism, however, which has a strongly oversocialized conception of the human being and thus hardly any concept of self at all, romanticism emphasizes agency and creativity in the process of self-formation and self-realization. Human beings are seen in their singularity, but the relation to others is an essential and inescapable part of their understanding of their own selves.

Charles Taylor's inquiry into *The Sources of the Self* is a most recent and forceful restatement of this conception. Taylor starts out from the familiar argument that the advent of modernity

indicates that common frameworks for moral evaluation can no longer be presumed to exist. The key subsequent contention is then that the ability and inclination to question any existing such framework of meaning does not lead into a sustainable position that would hold that no such frameworks are needed at all, a view he calls the 'naturalist supposition' (Taylor, 1989, p. 30). If such frameworks of meaning are what gives human beings identity, allows them to orient themselves in social and moral space, then they are not 'things we invent' and may as well not invent. They need to be seen as 'answers to questions which inescapably pre-exist for us,' or, in other words, 'they are contestable answers to inescapable questions' (Taylor, 1989, pp. 38, 40). Taylor develops here the contours of a concept of inescapability as part of a moral-social philosophy of selfhood under conditions of modernity. Meaning-centered conceptions of selfhood have recently been underlined as a basis of communitarian positions in moral and political philosophy, such as Sandel's concept (1982) of the 'encumbered self.'

Selfhood and Otherness

Arguably, these two concepts of selfhood remain within the frame of a debate in which the under- and the oversocialized views of the human being occupy the extreme points. The introduction of interaction and intersubjectivity in self-formation has created intermediate theoretical positions, and, possibly more importantly, they have allowed different accentuations of selfhood without making positions mutually incompatible. Nevertheless, the modernity-oriented view still emphasizes a self that acts upon the world, whereas the meaning-oriented view underlines the fact that the self is provided the sense of their actions by the world of which they are a part. Since the mid-1970s, in contrast, theoretical and empirical developments have tended to break up the existing two-dimensional mode of conceptualization.

On the one hand, the notion of a 'decentering of the subject' has been proposed mainly from poststructuralist discussions. On the other hand, the observation of both multiple and changing basic orientations in human beings has led to the proliferation of the – infelicitously coined – term 'postmodern identity' as a new form of selfhood. In both cases, a strong concept of self has been abandoned, in the one case on the basis of philosophical reflection, in the other, grounded on empirical observation. Both the ideas of a 'decentring' and of a 'postmodern self' question some major implications of the more standard sociological view of selfhood, namely the existence of the human self as a unit and its persistence as the 'same' self over time.

In the former perspective, the philosophical maxim of thinking identity and difference as one double concept, rather than as one concept opposed to another, is translated into sociological thinking as the need to think self and other as a relation, rather than as a subject and a context or object. Such notions rather underline the nonidentitarian character of being by pointing to the issue of 'the other in me' (Emmanuel Lévinas) as a question of co-constitution rather than of interaction. While emphasized in recent poststructuralist thought, similar ideas can be found, for instance, in Arendt's (1978, pp. 183–187) insistence on the 'two-in-one,' on the relation to oneself as another, as the very precondition for thought. In a broad sense, they go back to the ancient view of the friend as an 'other self.' And Theunissen (1977/1965) had already conceptualized self-other relations on the basis of an understanding of 'the Other' as referring to all 'concepts through which philosophy interprets the presence and present of the fellow/co-human being (*Mitmensch*) or of the transcendental original form of this human being.'

In one particular formulation, Cavell's reflections provide an example for a thinking about selfhood that does not presuppose an idea of identity, coherence, or consistency (Cavell, 1989, 1990). He cautions against 'any fixed, metaphysical interpretation of the idea of a self' and against the idea of 'a noumenal self as one's "true self" and of this entity as having desires and requiring expression.' In contrast, Cavell suggests that the 'idea of the self must be such that it can contain, let us say, an intuition of partial compliance with its idea of itself, hence of distance from itself' or, in other words, he advocates the idea of 'the unattained but attainable self' (Cavell, 1990, pp. 31, 34). Cavell proposes here a relation of the unattained and the attainable as constitutive for the self, that is, he makes the very question of attainability a central feature of a theory of selfhood.

Selfhood and Sociohistorical Transformations

The development of this threefold semantic space has considerably enriched the conceptualization and analysis of selfhood in the social sciences during the twentieth century. If one considers the three fields of inquiry as explorations of the various dimensions of selfhood, rather than as mutually exclusive perspectives, the question of the constitution of the human self emerges as a *problématique* that concerns all human beings and for which there may be a variety of processes which can be determined generally only in their forms but not in their results. As a consequence, however, it becomes much more difficult to conclude from the prevailing character of selfhood on social structure and political order. This has often been seen as a 'weakness' of symbolic interactionism, for instance, which Mead's view of the self is said to have inaugurated, as a social theory that allegedly cannot address issues of societal constitution. But by the same move Mead allows for and recognizes a plurality of selves that has returned to the center of discussion today – after the renewal of a regressive synthesis of identity and society in Talcott Parsons's work (to which – what is often overlooked – Erik Erikson contributed as well). The question of the relation between selfhood and society and politics thus needs to be rephrased as a question of comparative-historical sociology rather than merely of social theory.

Some indications as to how this relation should be understood can be found when reading the historical sociology of twentieth century societies in this light. The social upheaval during the second half of the nineteenth century with industrialization, urbanization and the phrasing of 'the social question' is often seen as a first 'modern' uprooting of established forms of selfhood, as a first massive process of 'disembedding' (Giddens, 1990). The development towards so-called mass societies during the first half of the twentieth century lets the question of the relation between individuation and growth of

the self emerge. Totalitarianism has been analyzed in terms of an imbalance between imposed individuation and delayed self-formation, the result having been the tendency towards 'escape from freedom' and into stable collective identities (Fromm, 1941; Arendt, 1958). The first three decades after the Second World War are then considered as a form of re-embedding of selves into the institutional frames of democratic welfare societies. Most recently, the indications of dissolution and dismantling of the rather comprehensive set of social institutions of the interventionist welfare state are one of the reasons to focus sociological debate again on questions of selfhood and identity. During this period, as some contributions argue, no longer continuity and coherence but transience, instability, and inclination to change are said to be marks of the important life orientations of contemporary human beings (see Shotter and Gergen, 1989; Lash and Friedman, 1992; Kellner, 1995). However, many of these analyses are challenged on grounds of the limited representativity of the empirical sample or on conceptual grounds.

Given the theoretical insights described above as the emergence of the threefold semantic space of selfhood, any attempt to offer a full-scale reformulation of the issue of the varieties of selfhood in different sociohistorical configurations would be adventurous. Forms of self-constitution and substantive orientations of human selves are just likely to be highly variable across large populations with varieties of experiences and sociocultural positions. However, the notion of recurring crises of modernity and the identification of historically distinct processes of disembedding and re-embedding could be the basis for a socially more specific analysis of the formation and stability of social selves (Wagner, 1994).

The social existence of the 'modern' idea that human beings construct their selves is what many societies have in common throughout the 1800s and 1900s. As such, it does not give any guidance in defining different configurations. Therefore, three qualifying criteria have been introduced. First, the existence of the idea of construction of selfhood still leaves open the question whether all human beings living in a given social context share it and are affected by it. The social permeation of the idea may be limited. Second, human beings in the process of constructing their selves may consider this as a matter of choice, as a truly modernist perspective would have it. In many circumstances, however, though a knowledge and a sense of the fact of social construction prevails, it may appear to human beings as almost natural, as in some sense pre-given or ascribed, which social self they are going to have. Third, the stability of any self one has chosen may vary. Such a construction of selfhood may be considered a once-in-a-lifetime occurrence, but may also be regarded as less committing and, for instance, open to reconsideration and change at a later age. These criteria widen the scope of constructability of selfhood. All conditions of construction have existed for some individuals or groups at any time during the past two centuries in the West. But the widening of the scope of construction may mark the transitions from one to another social configuration of modernity. These transitions entail social processes of disembedding and provoke transformations of social selves, in the course of which not only other selves are acquired but the possibility of construction is also more widely perceived.

Self: Philosophical Aspects

Carol Rovane, Columbia University, New York, NY, USA

Abstract

The first section of this article outlines the classical problem of personal identity that was originally posed by Locke and continues to generate philosophical debate. The next section discusses some of the distinctive social relations into which only selves can enter. The article then draws several analogies between such social relations and first-personal relations, and shows how these analogies point to the possibilities of group and multiple selves. It closes with some cautionary remarks about how overlooking these two possibilities can lead to confusions about methodological individualism.

This article focuses on two related ways in which philosophical reflection on the self may usefully be brought to bear in social science. One concerns the traditional problem about personal identity. The other concerns the distinctive kinds of social relations into which only selves can enter. Sustained reflection on the second issue reveals striking analogies between some of the social relations into which only selves can enter and certain first-personal relations that only a self can bear to itself. These analogies entail two possibilities that relate to the first issue concerning personal identity, namely, the possibility that there could be group selves who are composed of many human beings and the possibility that there could be multiple selves within a single human being. If the facts about group selves are not reducible to facts about their human constituents atomistically described, it might seem to follow that methodological individualism is false. But this follows only if we assume that the only individuals that exist are individual human beings, and this assumption is rendered false by the very possibility of group selves.

As an aside that there is a third way in which philosophical reflection on the self might conceivably be brought to bear in social science, which derives from a conception of the self as having a capacity for free choice and action. When the findings of social scientific investigation are presented as *laws* of human behavior, the question immediately arises whether selves, qua free agents, have the power to deviate from those laws – in other words, does it lie within our power to choose *not* to conform to certain scientific visions of what we are like? This question is closely allied to philosophical puzzles about the self that particularly intrigued Sartre, which concern whether the unity of the self – its numerical *oneness* – is necessarily undermined by any act of first-person reflection, due to the way in which the knowing *subject* that actively undertakes such reflection must consider its own self in a different, nonactive, mode as the passively known *object* of its reflection. Prima facie, it would seem that making the self into such an object is precisely what the social scientific stance invites us to do; and seconda facie, it would seem that what is thereby known may never be a complete story insofar as there is always an active self who is taking up that stance. These mysteries of the self fall under the heading 'freedom,' and although they are not entirely irrelevant to the main concerns of this article they deserve separate discussion. The focus here will be on other respects in which the essential *oneness* of the self is not a straightforward matter, and introduces complications for two fundamental concepts of the social sciences, namely, the concept of a social relation and the concept of the self as social relatum.

The Philosophical Problem about Personal Identity

To have a self is to be self-conscious in roughly the sense that Locke took to be the defining mark of the person. In his words, a person is "a thinking, intelligent being, that has reason and reflection, and can think itself as itself in different times and places" (Locke, 1979). In general, all of these capabilities – for thought, reason, reflection, and reflexive self-reference – tend to be lumped together by philosophers under the common heading of self-consciousness. Except in some generous accounts of animal intelligence, it is generally assumed that the only fully self-conscious beings are human beings.

Locke famously disagreed. This was not because he believed that there are other species of animal besides the human species whose members actually qualify as persons (though he did discuss at some length a certain parrot that was reported to have remarkable conversational abilities). It was rather because he thought that the condition of personal identity should not be understood in biological terms at all; it should be understood, rather, in phenomenological terms. As he put it, a person's identity extends exactly as far as its consciousness extends. He saw no reason why the life of a person so construed, as a persisting center of consciousness, should necessarily coincide with the biological lifespan of a given human animal. In defense of this distinction between personal and animal identity, he offered the following thought experiment: first, imagine that the consciousnesses of a prince and a cobbler are switched each into the other's body, and then consider who would be who thereafter. He thought that anyone who does consider this is bound to see that the identity of the prince is tied to his consciousness in such a way that he would remain the same person – would remain himself – even after having gained a new, cobbling body (similar remarks apply to the cobbler).

Many objections have been raised against Locke's argument and conclusion, and it remains a matter of serious dispute among philosophers whether he was right to distinguish the identity of the person from the identity of the human animal (Parfit, 1984; Perry, 1975; Rorty, 1979). Yet this philosophical

dispute has not drawn much attention from social scientists, who generally assume against Locke that the life of each individual self or person coincides with the life of a particular human being. The anti-Lockean assumption is so pervasive in the social sciences that it serves as common ground even among those who take opposing positions on the issue of methodological individualism – whether all social facts are reducible to facts about individuals or whether there are irreducibly social facts (*see* Individualism versus Collectivism: Philosophical Aspects; Methodological Individualism).

When Locke and neo-Lockeans set out to defend his distinction between the person or self and the human being, they have not generally tried to argue that there any *actual* instances of it; they have been content to argue for the *possibility* that a person's consciousness could be transferred from one human body to another – a possibility that they have tried to illustrate with various thought experiments. One drawback of Locke's original thought experiment about the prince and the cobbler is that it merely *stipulates* that two persons' consciousnesses are switched each into the other's body, without providing any supporting account of how this is supposed to happen. Subsequent thought experiments offered by neo-Lockeans have tried to do better on this score, by describing particular processes through which this might happen, such as brain transplantation or brain reprogramming. But it must be admitted that these added details belong more to the realm of science fiction than scientifically informed speculation, and so they do not give us any realistic expectation that what is being imagined will ever actually come to pass (Wilkes, 1988). It would appear to follow that social scientists may safely set aside the entire philosophical dispute about personal identity as irrelevant to their investigations, and retain their anti-Lockean assumption as the only realistic one on which to proceed, according to which the identity of an individual self is always the same as the identity of an individual human being.

Although it is indeed tempting to draw this conclusion, it would be a mistake to do so. Some new reasons have come to light for embracing a version of Locke's distinction, which are not derived from thought experiments but from a philosophical account of the nature of distinctively personal agency, and these reasons direct our attention to some *actual* instances of Locke's distinction that do potentially bear on the empirical concerns of social science. This will emerge over the course of the next several sections.

The Sociality of Selves: Rational Relations

Starting roughly with Hegel, various philosophers have mounted arguments to the effect that self-consciousness is a social achievement that simply cannot be possessed by beings who stand outside of all social relations (Wittgenstein, 1953; Davidson, 1984). The common conclusion of these arguments is overwhelmingly plausible, and it is clearly supported by a vast range of empirical work in developmental psychology. So even if none of the strictly philosophical arguments for the conclusion were wholly convincing, we could still take for granted the following well-confirmed empirical facts: self-conscious beings typically are social, and their social relations reflect their self-consciousness in interesting ways. These facts gave rise to a special field of study within micro-sociology during the last century, pioneered by Mead, called "symbolic interactionism" (Mead, 1934; Blumer, 1969).

In order to gain a full appreciation of the *philosophical* significance of the social dimension of self-consciousness, we must shift our attention away from the phenomenological dimension of it that Locke had made central in his analysis of the condition of personal identity, and shift our attention to another dimension of it that he emphasized in his initial definition of the person as a "a thinking, intelligent being, *with reason and reflection*." Obviously, one need not cite Locke as an authority in order to defend the point that exercising a capacity for reflective rationality is crucial for the achievement of selfhood, and that it is even more crucial than being the site of a single consciousness. But the point deserves careful elaboration, in order to expose some of its less obvious consequences.

Arguably, every sentient animal is the site of a single consciousness, even animals that cannot plausibly be said to either have or be a self – for example, wallabies and cockatoos. Locke's analysis of personal identity seems to suggest that what marks the difference between such animals and self-conscious beings is that the latter have a capacity for reflexive thought and reflexive reference – thoughts that are expressed in the first-person singular, with the pronoun 'I' – a pronoun whose reference must, it seems, be a self. The trouble with this suggestion is that if unself-conscious animals like wallabies and cockatoos can represent things at all (which some philosophers deny (Davidson, 1984)), it is very likely that some of their representations will function in ways that are characteristic of reflexive self-representations. Consider, for example, mental maps in which such animals represent their spatial relations to the various objects they perceive; such maps require a way to mark the distinction between their own bodies and other bodies, a distinction which is not inaptly characterized as the distinction between self and other (Evans, 1982).

Self-consciousness in the sense that goes together with selfhood involves a much more sophisticated sort of self-representation that incorporates a conception of oneself as a thinking thing and, along with it, the concept of thought itself. Armed with this concept, a self-conscious being can do more than represent itself; it can self-ascribe particular thoughts, and then also take up the critical perspective of reflective rationality toward its own thoughts.

Whenever selves in this full sense enter into social relations, they enter into relations of reciprocal recognition. Each is self-conscious; each conceives itself as an object of the other's recognition; each conceives the other as so conceiving itself (i.e., as an object of the other's recognition); each conceives both as having a common nature and, in so doing, each conceives both as so conceiving both (i.e., as having a common nature). Since this reciprocally recognized common nature is social as well as rational, it affords the possibility of the social exercise of rational capacities. Thus, corresponding to the capacity to ascribe thoughts to oneself, there is the capacity to ascribe thoughts to others; corresponding to the capacity to critically evaluate one's own thoughts there is the capacity to critically evaluate the thoughts of others; and together with all this comes another extraordinary social capacity, the capacity for specifically rational influence in which selves aim

to move one another by appealing to the normative force of reasons. Such rational influence is attempted in virtually every kind of social engagement that takes place among selves, including engaging in ordinary conversation and argument, offering bribes, lodging threats, bargaining, cooperating, and collaborating. In all of these kinds of engagement reasons are offered up in one guise or another in the hope that their normative force will move someone else.

Analogies between First-Personal and Social Relations

It is because selves have a rational nature that analogies arise between their first-personal relations to their own selves and their social relations to one another. Here are three examples.

Critical Evaluation

It is a platitude that the principles of rationality are both impersonal and universal. They lay down normative requirements that *anyone* must meet in order to be rational, and they constitute the standards by which *everyone* evaluates their own and everyone else's rational performances. It follows that when we evaluate our own thoughts by these standards, we are really considering them as if they were anyone's – which is to say, as if they were not our own. We sometimes describe this aspect of critical self-evaluation with the phrase 'critical distance.' There is a specific action by which we accomplish this distancing: we temporarily suspend our commitment to act on our thoughts until after we have determined whether keeping the commitment would be in accord with the normative requirements of rationality. If we determine that it would not be in accord with those requirements, then the temporary suspension of our commitment becomes permanent, and our critical distance on our thoughts gives way to literally disowning them. But before getting all the way to the point of disowning our thoughts we must first have gotten to a point where our relations to our thoughts are rather like our relations to the thoughts of others. For, whether we decide to disown the thoughts under critical scrutiny or to reclaim them, the normative standards on the basis of which we do so are necessarily conceived by us as impersonal and universal. In consequence, there is a straightforward sense in which we are doing the same thing when we apply the standards to our own thoughts and when we apply them to the thoughts of others. There is this difference, though: whereas self-evaluation involves distancing ourselves from our own thoughts, evaluating the thoughts of others involves a movement in the opposite direction. We must project ourselves into their points of view so that we can appeal to their own sense of how the principles of rationality apply in their specific cases. This sort of criticism that involves projection is sometimes called 'internal criticism,' in contrast with the sort of 'external criticism' that proceeds without taking into account whether its target will either grasp it or be moved by it (Williams). This difference between internal criticism of others and self-criticism – the difference between projection and distancing – does nothing to undermine the analogies between them. On the contrary, for by these opposite movements two distinct selves can bring themselves to the very same place. That is, when one self projects itself into another's point of view for the purposes of internal criticism, it can reach the very same place that the other gets to by distancing itself from its own thoughts for the purposes of self-criticism. Moreover, there is a sense in which what the two selves do from that place is not merely analogous, but the very same thing. Each of the two selves brings to bear the same critical perspective of rationality on the same particular self's thoughts. The only difference that remains is that in the one case it is a social act directed at another, whereas in the other case it is a self-directed act.

Joint Activities

Just as internal criticism of another replicates what individual selves do when they critically evaluate themselves, so also joint activities carried out by many selves may replicate the activities of an individual self. For the purposes of such activities, distinct selves need to look for areas of overlap between (or among) their points of view, such as common ends, common beliefs about their common ends, and common beliefs about how they might act together so as to realize those ends. These areas of commonly recognized overlap can then serve as the basis from which the distinct selves deliberate and act together and, as such, the areas of overlap will serve as a common point of view that is shared by those selves. Whenever distinct selves do deliberate together from such a common point of view, they will be guided by the very same principles that ordinarily govern individual deliberation, such as consistency, closure (the principle that one should accept the implications of one's attitudes), and transitivity of preferences. All such principles of rationality taken together define what it is for an individual to be fully or optimally rational. For this reason, they generally apply separately to each individual but not to groups of individuals. (Thus, different parties to a disagreement might be individually rational even though they contradict each other, but they cannot be individually rational if they each believe contradictions.) The one exception is joint activities in which such groups of individuals deliberate together from a common point of view. To take a limited example, you and I might deliberate individually about a philosophical problem or we might do so together. If we do it individually, each of us will aim to be consistent in our reasoning because that is what the principles of rationality require of us individually. But these principles do not require us to do this together; which is to say, you and I may disagree about many things without compromising our ability to pursue our individual deliberations from our separate points of view in a completely rational manner. What would be compromised, however, is our ability to work on a philosophical problem together. We cannot do that without resolving at least some of our disagreements, namely, those that pertain to the problem. This means that if we truly are committed to working on the problem together, then we should recognize a sort of conditional requirement of rationality, a requirement to achieve as much consistency between us as would be necessary to carry out our joint project. Although we need not achieve overall consistency together in order to do this – that is, we need not agree on every issue in every domain – nevertheless, we must resolve our disagreements about the relevant philosophical matters. When we resolve these disagreements we will be doing within a limited

domain the very same thing that individuals do within their whole points of view when they respond to the rational requirement of consistency. The same holds for the other principles of rationality such as closure and transitivity of preferences. In general, whenever distinct individuals pursue ends together, they temporarily cease deliberating and acting separately from their individual points of view in order to act and deliberate together from their common point of view. Correlatively, they strive to achieve by social means within a group – albeit in a limited domain – the very sorts of rational relations and outcomes that are characteristic of the individual self (Korsgaard, 1989).

Rationality over Time

Although there is some sense in which individual points of view are extended in time, the deliberations that proceed from such points of view always take place in time from the perspective of the present. The question immediately arises, why should an individual take its future attitudes into account when it deliberates from the perspective of the present? The question becomes poignant as soon as we concede that an individual's attitudes may change significantly over time. Thus, consider Parfit's Russian nobleman who believes as a young man that he should give away all of his money to the poor, but who also believes that he will become much more conservative when he is older and will then regret having given the money away. What should he do? Parfit answers as follows: if he recognizes any normative pressure toward an altruistic stance from which he is bound to take the desires of others into account, then he must extend that stance to his own future desires as well – regardless of the fact that he now disapproves of them (Parfit, 1984). Other philosophers have also insisted on parity between the normative demands of prudence and altruism. Among moral philosophers, the parity is often taken in the positive way that Parfit does, as showing that we have reason to be both prudent and altruistic (Sidgewick, 1981; Nagel, 1970). But some philosophers have taken it in a negative way, as showing that we lack reason to be either. According to them, it follows from the fact that deliberation always proceeds from the perspective of the present that rationality does not require us to take our own future attitudes into account any more than it requires us to take the attitudes of others into account. If they are right, then the rational relations that hold within an individual over time are comparable to social relations within a group (Elster, 1979; Levi, 1985). However, anyone who is struck by this last suggestion – that an individual over time is, rationally speaking, analogous to a group – would do well to bear in mind what the first two analogies brought out, which is that the social exercise of rational capacities within a group can literally replicate individual rationality.

Group Selves and Multiple Selves

It might seem implausible that the normative analogies between first-personal and social relations could ever jeopardize the metaphysical distinction between them, which is grounded in whatever facts constitute the identity and distinctness of selves. According to Locke, these facts are phenomenological; according to his opponents, the facts are biological. In both the cases, the metaphysical facts on offer appear to ground a distinction between first-personal and social relations, which are guaranteed to hold no matter how deep and pervasive the analogies between these two sorts of relations might be at the normative level.

Yet there is a way of thinking about the self that calls this into question. It is the very way of thinking that predominated in Locke's initial definition of the person as a being with "reason and reflection." When we emphasize this rational dimension of the self, we will find it natural to use a normative criterion in order to individuate selves. According to this normative criterion, we have one self wherever we find something that is subject to the normative requirements that define individual rationality. There is some disagreement among philosophers about exactly what these requirements are. But, even so, we can say this much with confidence: it is a sufficient condition for being a rational individual who is subject to the requirements of rationality that the individual have some conception of what those requirements are and is in some degree responsive to them – in the sense of at least trying to meet them when it deliberates and accepting criticism when it fails to meet them (Bilgrami, 1998). Of course, such criticism might issue from without as well as within, since a rational individual in this sense would certainly have the conceptual resources with which to comprehend efforts by others to wield rational influence over it. This ensures that there is a readily available public criterion by which such rational individuals can be identified for social purposes: there is one such individual wherever there is an interlocutor whom we can rationally engage. It must be admitted that, due to the analogies between first-personal and social relations, the boundaries between such individuals will not always be clear. Yet this does not mean that the normative conception of the self is inadequate or unworkable. It only means that the conception has unfamiliar and, indeed, revisionist consequences. For, if we press the analogies between first-personal and social relations to their logical limit, it follows that there can be group selves comprising many human beings and, also, multiple selves within a single human being (Rovane, 1998).

Take the group case first. We have seen that, for the purposes of joint activities, distinct selves must find areas of overlap between their individual points of view that can then serve as a common point of view from which they deliberate and act together. We have also seen that such joint deliberations replicate individual rationality in degree. Now, suppose that this were carried to the following extreme: a group of human beings resolved to engage only in joint activities; accordingly, they resolved to rank all of their preferences about such joint activities together and to pool all of their information; and finally, they resolved always to deliberate jointly in the light of their jointly ranked preferences and pooled information. The overlap between their points of view would then be so complete that they no longer had separate points of view at all. They would still have separate bodies and separate centers of consciousness. But, despite their biological and phenomenological separation, they would nevertheless all share a single rational point of view from which they deliberated and acted *as one*. Consequently, they could also be rationally engaged in the

ways that only individual selves can be engaged. There is good reason to regard such a group as a bona fide individual in its own right (Korsgaard, 1989; Rovane, 1998; Scruton, 1989; List and Pettit, 2011).

Now take the multiple case. Recall that it might be rational for an individual to disregard its future attitudes when it deliberates about what to do in the present, in just the way that it might be rational (though possibly immoral) to disregard the attitudes of others. If the normative demands of rationality are thus confined to one's own present attitudes, then one's future self will be no more bound by one's present deliberations than one is presently bound to take one's future attitudes into account. In other words, one's future self will be free to disregard any long-term intentions or commitments that one is thinking of undertaking now. The point is not that there are no such things as long-term intentions or commitments. The point is that when one makes them one does not thereby bind one's future self in any causal or metaphysical sense. It is always up to one's future self to comply or not as it wishes, and one could not alter this aspect of one's situation except by undermining one's future agency altogether. Although this may seem alarming, it does not follow that individual selves do not endure over time. All that follows is that the unity of an individual self over time is constituted by the same sorts of facts that constitute the unity of a group self. Just as the latter requires shared commitments to joint endeavors so too does the former, the only difference being that the latter involves sharing across bodies while the former involves sharing across time. This serves to bring out that the metaphysical facts in terms of which Locke and his opponents analyze the identity of the self over time are, in a sense, normatively impotent. The fact that there is a persisting center of consciousness, or a persisting animal body, does not suffice to bind the self together rationally over time. And, arguably (though this is more counter-intuitive), such facts do not even suffice to bind the self together rationally in the present. That is why we are able to understand the phenomenon of dissociative identity disorder, formerly known as multiple personality disorder. Human beings who suffer from this disorder exhibit more than one point of view, each of which can be rationally engaged on its own. Since none of these points of view encompasses all of the human host's attitudes, there is no possibility of rationally engaging the whole human being. At any given time one can engage only one part of it or another. Each of these parts functions more or less as a separate self, as is shown precisely by the susceptibility of each to rational engagement on its own. Although these multiple selves cannot be rationally engaged simultaneously, there is good reason to suppose that they nevertheless exist simultaneously. While one such self is talking, its companions are typically observing and thinking on their own (this generally comes out in subsequent conversation with them). Furthermore, these multiple selves who coexist simultaneously within the same body are sometimes 'co-conscious' as well – that is, they sometimes have direct phenomenological access to one another's thoughts. But their consciousness of one another's thoughts does not put them into the normative first-person relation that selves bear to their own thoughts; for they do not take one another's thoughts as a basis for their own deliberations and actions. Thus neither their shared body nor their shared consciousness suffices to bind multiple personalities together in the sense that is required by the normative conception of the self. On that conception, they qualify as individual selves in their own rights (Braude, 1995; Rovane, 1998; Wilkes, 1988).

Between these two extreme cases of group and multiple selves, the normative conception provides for a wide spectrum of cases, in which centers of rational unity are exhibited within and among human beings. The conception says that whenever there is the sort of rational unity that is characteristic of individual rationality, there is a rational being with its own point of view who can be rationally engaged as such, and who therefore qualifies as an individual self in its own right.

Implications for Methodological Individualism

It is not the case that all of the facts about the Columbia Philosophy Department can be reduced to facts about its members atomistically described. Nor is it the case that all of the facts about that department can be explained by appealing to facts about its members atomistically described. Why? Because sometimes the members of the department stop reasoning from their own separate human-size points of view and begin to reason together from the point of view of the department's distinctive projects, needs, opportunities, and so on. When the members of the department do this, they give over a portion of their human lives to the life of the department in a quite literal sense, so that the department itself can deliberate and act from a point of view that cannot be equated with any of their individual points of view. Social scientists might naturally regard these claims about the Columbia Philosophy Department as contradicting methodological individualism, but that is because they make the anti-Lockean assumption that the only individuals there are or can be are individual human beings. Given the assumption, they are bound to interpret the above claims about the Columbia Philosophy Department – that the facts about it cannot be properly described or explained by appealing exclusively to facts about its individual human members atomistically described – as pointing to irreducibly social phenomena. However, this interpretation fails to take account of the way in which the department instantiates the rational properties that are characteristic of the individual self (vs a social whole).

Self-Categorization Theory

S Alexander Haslam, School of Psychology, University of Queensland, St Lucia, QLD, Australia

Abstract

Self-categorization theory is a theory about the functioning of the self that provides three key insights into social behavior. First, social identity (a shared sense of 'us') is what makes group behavior possible. Second, the self system reflects a dynamic context-sensitive categorization process through which people see themselves as either sharing category membership with others or not. Third, shared self-category membership is the basis for mutual social influence. In these ways, shared social identity is understood as the basis for all forms of productive social interaction between people – in particular, those that entail cooperation, organization, and leadership.

Self-categorization theory "is a set of related assumptions and hypotheses about the functioning of the social self-concept (the concept of self based on comparison with other people and relevant social interaction)" (Turner, 1987: p. 42). The theory is a development of *social identity theory* – a theory which examines the way in which intergroup relations are structured by people's *social identity* (the sense of 'us' that reflects their self-categorization in terms of group membership; Tajfel and Turner, 1979). Together these two theories comprise the *social identity approach* (Turner, 2004; Reicher et al., 2010); however, where social identity theory is oriented to the explanation of a particular type of group behavior (intergroup discrimination), self-categorization theory is concerned with "how individuals are able to act as a group at all" (Turner, 1987: p. 42).

In this regard, one important shortcoming of social identity theory is that it offers only a limited analysis of the cognitive aspects of social identity. When do people categorize themselves in terms of group membership (as 'us' and 'we') rather than as individuals (as 'I' and 'me')? What leads to self-categorization in terms of one group membership rather than another? What is the nature of these social self-categorizations, and how does the self-categorization process transform a person's psychology and behavior? Despite the fact that the construct of social identity is obviously its core focus, social identity theory provides no real answers to questions like these. It was therefore to address such questions that self-categorization theory was developed by Turner and his colleagues in the 1980s (Turner, 1982, 1985; Turner et al., 1987, 1994). The result is a theory that has enormous and profound implications for psychology, primarily because it allows us to understand not only how individual minds are structured by social group memberships, but also how this structuring provides a basis for individuals to achieve otherwise unimaginable feats of collective organization and concerted action.

Depersonalization and Self-Stereotyping

Formative work on self-categorization theory focused on unpacking the cognitive substrates of social identity. In particular, Turner (1982) presented a more complete explanation of the process whereby people moved from seeing themselves and the world in interpersonal terms (e.g., 'me' interacting with 'you'), to seeing it in intergroup terms ('us' interacting with 'them'; as hypothesized by Tafjel's (1978), interpersonal–intergroup continuum). A key insight here is that it is a person's self-categorization in terms of social identity that actually *allows* intergroup behavior to take place. As Turner famously put it, "social identity is the cognitive mechanism that makes group behaviour possible" (p. 21; see also Haslam et al., 2003).

Turner went on to specify a *psychological process* associated with self-categorization in terms of social identity. Termed *depersonalization*, this refers to a process of *self-stereotyping* through which *the self comes to be perceived as categorically interchangeable with other in-group members*. Here individuals understand themselves and others not as differentiated individuals but as exemplars of a common in-group. This in turn plays a key role in regulating social behavior because it leads group members to act, not as unique individuals, but instead with reference to goals and norms that they share. This means, for example, that a person can act as a member of a given group (e.g., as a firefighter) only to the extent that they define themselves less as a unique individual (e.g., as someone who is married to Sam and likes woodwork) and more as someone who is categorically interchangeable with other firefighters and whose behavior is regulated by norms associated with that social category (e.g., to wear a uniform, to observe certain safety protocols, to be loyal to one's unit).

The Self-Categorization Process: Key Assumptions and Hypotheses

In suggesting that group behavior follows from an act of self-stereotyping, self-categorization theory points to the role that *categorization* – and more specifically *self*-categorization – plays in social perception and behavior. This was formalized in a number of core assumptions and related hypotheses of which five are key (Turner, 1985; Turner et al., 1987).

First, cognitive representations of the self are argued to take the form of *self-categorizations*. That is, the self is seen as a member of a particular class or category of stimuli. As such, it

is perceived to be (1) more or less equivalent to other stimuli in that category, and (2) more or less distinct from stimuli in other categories. So, for example, when a woman categorizes herself as a geographer she acknowledges her equivalence to other geographers and her difference from, say, sociologists or geologists.

Second, self- and other categories exist at different levels of abstraction with higher levels being more inclusive. Lower-level categories (e.g., geographer, geologist) can be subsumed within higher ones (e.g., earth scientist) and are defined in relation to comparisons at that higher level. For analytical purposes, the theory differentiates between three important levels of the social self-concept: self-categorization (1) at the superordinate *human* level as a human being (in contrast to other species), (2) at the intermediate *social* level as an in-group member (as distinct from out-groups), and (3) at the subordinate *personal* level as a unique individual (different from other relevant in-group members). Importantly, level of category abstraction is a relative concept – so more than one level of social self-category will typically be available for any given person. For example, our geographer may define herself in terms of social self-categories that are more or less abstract – as a scientist, as an earth scientist, or as a social geographer. Importantly, too, self-categories at all levels of abstraction are equally 'real' and just as much a reflection of a person's 'true' self. No one level of self-categorization is inherently more appropriate, useful, or valid than another and hence none is in any sense more fundamental to who or what the person is. This proposition challenges a general assumption in psychological theory which accords privileged status to personal identity – as if a person's *true* self is defined only by their individuality.

Third, the formation and salience (i.e., the cognitive activation) of any self-category is partly determined by comparisons between stimuli at a more inclusive level of abstraction. More specifically, the formation of self-categories is argued to be a function of the *metacontrast* between interclass and intraclass differences. This means that within a frame of reference comprised of various salient stimuli, the likelihood of any given collection of stimuli being perceived as a categorical entity increases to the extent that their difference from each other is perceived to be less than the difference between them and all other stimuli. So, for example, a geographer and a geologist are more likely to be seen – and see themselves – to share social identity as scientists when they are encountered in a context that includes nonscientists. This is because here the differences between them will be seen as relatively small compared to those between them and the nonscientists. In this way, metacontrast *contextualizes* categorization by tying it to in-the-moment judgments of *relative differences*. It also means that a person's categorical representation of exactly the same social stimuli will vary as a function of comparative context. Whether you and I see ourselves as 'us' will depend in large part on how different we see ourselves as being from the *other people* we are conscious of in a given setting.

Fourth, just as the metacontrast principle is a partial determinant of *which* categories perceivers use to represent a given stimulus array, so too it is a partial determinant of the *internal structure* of those categories. Following cognitive theorizing (e.g., Rosch, 1978) categories are assumed to have an internally *graded structure* such that some features of a category (i.e., particular behaviors, attributes, or individuals) define it better than others. This means that people differ in the extent to which they are perceived to be representative or *prototypical* of groups in the same way that a dog is generally more representative of the category 'pet' than a snake. More specifically, it follows from the metacontrast principle that any particular category member will be perceived to be more prototypical of a category to the extent that he or she is less different from other members of that category than from other social stimuli that are salient in a given context. Again, then, self-categorization theory predicts that the prototypicality of exactly the same exemplar for exactly the same category – and hence their capacity to represent what that category means and stands for – will vary as a function of the social context within which categorization takes place.

Finally, fifth, the salience of a categorization at a particular level of abstraction leads to the *accentuation* of perceived intraclass similarities and interclass differences between people as defined by their category membership at the same level. In this way, patterns of accentuation are reflections of people's categorical interchangeability. For example, if a woman's social self-category 'geographer' becomes salient, other geographers will be perceived to be more similar to each other (and her) and more different from other nongeographers (whose similarity to each other will also be accentuated) on dimensions that are seen to define membership of those categories (e.g., commitment to the scientific method).

Perceiver Readiness and Fit as Determinants of Social Identity Salience

To answer one of the questions we posed earlier, the above ideas allow us to understand exactly what factors dispose people to act in terms of a particular social self-categorization. When will an employee in an organization see and act in terms of the organization as a whole, or in terms of the department or team to which they belong, or as an individual? Answering such questions is extremely important, because it is apparent that people are capable of acting at *all* these levels, but that the *particular* level at which they define themselves has distinctive implications both for their own behavior and for the functioning of the organization as a whole.

To address this issue, the principles of self-categorization theory were formally applied to the analysis of social identity salience by (Oakes, 1987; Oakes et al., 1991; Turner, 1985). Following Bruner (e.g., 1957), it was argued that one crucial determinant of social category salience is *fit* – the degree to which a social categorization appears to be a sensible way of organizing and making sense of social stimuli (i.e., people and things associated with them). Fit has two components: comparative and normative.

Comparative fit is defined by the principle of metacontrast discussed above. This leads us to expect that a person will define themselves in terms of a particular self-category to the extent that the differences between members of that category on a given dimension of judgment are perceived to be

smaller than the differences between members of that category and others that are salient in a particular context. If our (female) geographer was surrounded by psychologists and other geographers, she would tend to define herself as a geographer only if the differences between the two groups appeared to be larger than the differences within them – which, for example, is more likely to be the case at a science conference than at a football match. *Normative fit* reflects the fact that in order to represent sets of people as members of a given category, the differences between them must not only appear smaller than the differences between them and others (comparative fit), but the *nature* of these differences must also be consistent with a perceiver's expectations about the categories. Our geographer at the science conference will be unlikely to classify participants as geographers and psychologists (or to act as a geographer herself) if the members of these two groups are seen to differ from each other in ways that are completely unexpected – perhaps if the geographers are concerned only with mental processes and the psychologists only with space.

Importantly too, the principles of fit also determine category salience in interaction with *perceiver readiness* (or *accessibility*; Oakes et al., 1994; Turner et al., 1994). Individuals do not engage in social encounters by mechanically processing information about similarities and differences from scratch in order to decide whether a person is one of us. Categorization also depends on the expectations, goals, and theories that perceivers *bring* to a given context – many of which derive from their previous group encounters. We thus organize and construe the world in ways that reflect the groups to which we belong and in this way *social histories* lend stability and predictability to our experience (Oakes et al., 1994; Reicher, 1996). *Identification* with a group – the extent to which the group is valued and self-involving and contributes to an enduring sense of self – is therefore one particularly important factor which affects a person's readiness to use a given social category in order to define themselves (e.g., Ellemers et al., 1997; Turner, 1999). Among other things, this means that when we identify strongly with a given group, we more readily interpret the world, and our place within it, in a manner consistent with that group's values, ideology, and culture. For this reason alone, social identification has proved to be an important construct in both social and organizational psychology and a number of researchers have developed scales that attempt to measure both its nature and strength.

Social Influence as a Determinant of Organized Social Behavior

Self-categorization theory's analysis of social identity salience is directed to the explanation of social–psychological phenomena that are often studied by looking at the responses and perceptions of noninteracting individuals. Significant as it is, such analysis therefore makes only a partial contribution to an understanding of social behavior that involves *structured social interaction*. Importantly though, the dynamic processes of self-categorization described above do not just affect the perception of individuals in the abstract. They are also assumed to have ongoing consequences for the *active coordination* of individuals' perception and behavior.

In this regard, a key assertion of self-categorization theory is that social self-categorizations serve to regulate individual cognitive activity not only by providing a shared perspective on social reality but also by providing a basis for mutual *social influence* (Turner, 1987, 1991). This is because when people perceive themselves to share category membership with another person in a given context they not only *expect to agree* with them on issues relevant to their shared identity but are also motivated to *strive actively to reach agreement* on those issues. Where only geographers and psychologists are present, a single geographer and a single psychologist may define themselves in terms of distinct social self-categories and expect to have different views, intentions, and goals. But if they meet in a context that also includes people from very different backgrounds (e.g., artists, politicians) they are more likely to redefine themselves in terms of a higher-order *shared* social self-categorization (e.g., as social scientists) that provides them with a relatively common perspective and which motivates them to coordinate that perspective further through discussion, persuasion, negotiation, and argument.

Self-categorization theory argues that social influence of this form is *necessary* because it is not possible for a person to establish the subjective validity and correctness of their beliefs simply through 'independent' activity. In this way, other members of the groups to which we see ourselves as belonging (those who contribute to our sense of 'we-ness' – i.e., in-group members) serve as essential reference points for our own perception. Moreover, it is precisely through individuals' identification of, and conformity to, norms that are perceived to be shared with others in a particular context that their potentially idiosyncratic views become socially organized and consensual. In other words, it is through this process that individual views are coordinated and transformed into *shared* values, beliefs, and behaviors. These values and beliefs also have particular force in the world (e.g., in the form of shared stereotypes) because they are no longer experienced as subjective but instead articulate a common, as-if-objective view (Haslam et al., 1998). In this way, what had been simply *personal opinion* and contingent belief now becomes *social fact* – so that, for example, '*I think* they are stupid and lazy' now becomes '*they are* stupid and lazy.'

Indeed, at the most general level, we can see that it is through these categorization-based processes of influence that low-level individual inputs are transformed into higher-order group products. These have emergent higher-order properties which ensure that the group whole is qualitatively different from ('more than') the sum of its individual parts. Moreover, it is also through this process that social identity becomes a world-making and world-changing resource.

Tests and Applications of Self-Categorization Theory

Within social psychology, early work on self-categorization theory elaborated upon the implications of depersonalization

for social perception and behavior. In particular, Turner et al.'s (1987) milestone text, *Rediscovering the Social Group*, provided novel and important insights into a broad range of social psychological topics and issues. Some of these – most obviously *group formation*, *cohesiveness*, and *stereotyping* – had been of long-standing interest to social identity theorists. However, the theory also provided a radically new analysis to a host of other topics, in particular, *group polarization* (e.g., McGarty et al., 1992) and *crowd behavior* (e.g., Reicher, 1987).

Subsequent strands of research confirmed the capacity for people's self- (and other) stereotypes to respond fluidly to changes in comparative context in the ways predicted by the metacontrast principle (e.g., Doosje et al., 1998) and pointed to the ability of these same contextual features to impact upon the internal structure of social categories. Other early work showed how patterns of stimulus accentuation serve to reflect the perceived interchangeability of category members (e.g., Haslam and Turner, 1992; Hogg and Turner, 1987) and indeed how they structure perceptions of the individual person (e.g., their *personality*; Reynolds et al., 2010).

The theory's analysis of social influence also fed into the analysis of an array of social and applied phenomena (especially *organizational behavior*; e.g., Haslam, 2004). In particular, it has been used to inform theorizing around the topics of cooperation, *communication*, *negotiation*, group decision making, and *stress*. However, probably the largest area of work in which the theory's ideas have been developed and tested relates to the study of *leadership* (e.g., Ellemers et al., 2004; Haslam et al., 2011; Hogg, 2001; Turner and Haslam, 2001). The key insight here is that leadership is not, as commonly supposed, a property that resides in a person's character *as an individual*. Rather it results from a leader's capacity to embody what a particular group means to its members in any given context. The capacity for leadership thus rests on individuals' ability to be seen as prototypical of a shared social identity and to exert influence over other group members on this basis. In other words, it is only when leaders are seen as embodying 'who we are' that their leadership stimulates followership.

As such work has developed, key elaborations of self-categorization principles have increasingly demonstrated that these processes of social categorization and influence do not simply occur within the heads of individuals, but also take place 'out there' in the social world. In this way, a great deal of research has explored the entrepreneurial and public dimensions of social identities as they are crafted by would-be leaders and contested in social interaction (e.g., Reicher and Hopkins, 2001). This work has served to elaborate and clarify the *dynamic* nature of self-categorization principles and the social identity approach more generally. It shows not only that (and how) self-categorization processes *respond* to social reality, but also that (and how) they are the means by which that reality is *transformed* – in particular, through the development and exercise of group-based *power* (Reicher, 1996; Turner, 2005). In this way, the theory speaks not only to the social dimensions of thinking and seeing but also to the political process of collective action and social change.

Abstract

Self-concept is one of the oldest and most important constructs in the social sciences. It is also at the heart of the positive psychology revolution focusing on how healthy, normal, and exceptional individuals can get the most from life. We begin by distinguishing between an historical unidimensional perspective that focuses on self-esteem and a more recent multidimensional, hierarchical perspective that distinguishes between specific facets of self (e.g., academic, social, physical, and emotional). In this article we review developmental, educational, and personality perspectives of self-concept, gender differences, theoretical models, and empirical research on the reciprocal effects relating self-concept and performance, frame of reference effects based on social and dimensional comparisons that influence the formation of self-concept, and the juxtaposition between multidimensional perspectives of personality and self-concept.

Self-Concept: History and Significance

Self-concept is one of the oldest and most significant constructs in the social sciences. Highlighted by William James (1890/1963), self-concept today is viewed as a multidimensional, hierarchical construct with highly differentiated components such as emotional, physical, social, and academic self-concepts. Research has continually shown self-concept to be a critical construct in the attainment of academic achievement (Chen et al., 2013; Marsh and Craven, 2006; Pinxten et al., 2010), social and personal adjustment in children and adolescents (Harter, 1990), elite athlete success (Marsh and Perry, 2005), parent–adolescent relations (Barber et al., 2003), bullying (Marsh et al., 2004), approaches to learning (Burnett et al., 2003), and emotional adjustment and socialization (Donahue et al., 1993).

As such, enhancing self-concept is a major goal in many domains, including health, education, and the social services. According to Shavelson et al. (1976), self-concept is best thought of as a person's self-perceptions that are formed through experience and interpretations of one's environment, and incorporates feelings of self-worth, self-confidence, ability, and competence. Notably, self-concept is particularly susceptible to evaluations of significant others, reinforcements, and attributions for one's own behavior (Marsh, 2007). Additionally, not only is self-concept important as an outcome, but is also an important mediating factor that facilitates the attainment of other desirable outcomes (Shavelson et al., 1976).

The construct of self-concept has had a long and illustrious history, dating back to Socrates and Plato and to Bandura and Rogers in the present day (see Hattie, 1992). However, it can be argued that the current understanding of self-concept as a multidimensional construct can be traced back to William James (1890/1963). In his seminal work, The Principles of Psychology, James proposed the self as both multifaceted and hierarchical, "with the bodily self at the bottom, the spiritual self at the top, and the extracorporeal material selves and the various social selves between" (p. 313). This assertion, along with James' distinction between the self-as-knower (the I) and the self-as-known (the Me), played an important role in developing self-concept theory.

However, after the promising start by James, advances in self-concept theory, research, and measurement were slow and wrought with conceptual and methodological problems. Marsh (2007) proposed that the root of these problems may have been that terms such as self-concept were already so entrenched in the psychological vernacular and so widely used in everyday conversation that there was already an assumption that the paradigm was understood. Consequently, researchers may not have been motivated to explore theoretical definitions of the construct or to develop a systematic evaluation of self-concept measures (Marsh et al., 1988). This is reflected in the criticisms of pre-1980 self-concept research, which notes the dearth of sound measurement instruments, inherent methodological problems, and a pervasive inconsistency in reported results (e.g., Shavelson et al., 1976; Wylie, 1979).

Self-Concept: A Unidimensional or Multidimensional Construct?

Although James originally conceived self-concept as a multidimensional construct, there has been much debate on the value of unidimensional perspectives that emphasize a single, global domain of self-concept, often referred to as self-esteem, versus multidimensional perspectives based on multiple distinct components of self-concept (Marsh and Craven, 2006). Early self-concept research was generally dominated by a unidimensional perspective, where self-concept was represented by a single, general self-esteem score. However, this approach was criticized on the basis that a unidimensional perspective of self-concept does not allow researchers to capture the richness or specific insight that the various components of self-concept have to offer (Rosenberg et al., 1995).

It was not until Shavelson et al.'s (1976) seminal work that a multidimensional perspective again came to the forefront of self-concept research. After conducting an extensive review of

the self-concept literature, Shavelson et al. formed their own model of self-concept that was both multidimensional and hierarchical. Shavelson et al. posited a general self-concept encompassing all aspects of the self, which was then divided into academic and nonacademic self-concepts. At the next level, these self-concepts were further divided. For example, academic self-concept was further divided into self-concepts in specific subject areas (e.g., mathematics and English).

However, continued research suggested there were some weaknesses in Shavelson et al.' (1976) proposed model (see Byrne and Shavelson, 1996). This led Marsh and Shavelson (1985) to revise the model that provided a more highly differentiated view of self-concept than previous conceptions. For example, this model proposed higher-order academic factors of academic self-concept (e.g., mathematics and verbal) to explain self-concepts in specific school subjects, rather than the single dimension of academic self-concept initially proposed by Shavelson et al. Both the Shavelson et al. model and the Marsh–Shavelson revision are important, as they paved the way for the development of today's multidimensional self-concept instruments, which arguably formed the basis for considerable advances in the theoretical and methodological quality of self-concept research, as well as providing for stronger interventions (Craven et al., 1991; Marsh and Craven, 1997; Marsh and Shavelson, 1985).

The multidimensional perspective of self-concept has now been applied to a variety of settings, especially in the areas of education (Marsh, 1993) and sport (Fox and Corbin, 1989; Marsh, 2002). Importantly, the findings of all these studies have demonstrated the value of a multidimensional perspective over a global measure of self-esteem, especially in terms of predictive, convergent, and discriminant validity (Marsh, 2007). In addition, more recent research using a multidimensional perspective has proved valuable in the areas of bullying (Marsh et al., 2001b) and obesity and body image (Marsh et al., 2007).

Developmental Perspectives

Self-concept has been posited as a critical aspect of the social and emotional development of children by a number of researchers (Marsh et al., 2005a, 2002a). Thus, the issue of self-concept is a central concern to developmental psychologists. Researchers have been particularly interested in charting how self-concept develops with age. However, while it is clear that self-concept plays an important role in childhood development, there is less clarity regarding the age that children become able to report their self-concepts. Marsh et al. (2005a) argued that this has largely been due to a lack of appropriate instruments to adequately measure the self-concepts of young children.

The development of self-concept scales designed especially for young children have shed some light on how self-concept is experienced in early childhood. Using a version of the Self Description Questionnaire (SDQ) adapted for young children, Marsh et al. (2002a) demonstrated that preschool-aged children are able to distinguish between multiple dimensions of self-concept at a younger age than suggested by previous research. However, measures of verbal and mathematics self-concepts were highly correlated (0.73) in comparison to the typical small correlations between mathematics and verbal self-concepts evidenced in older children (Marsh, 1986; Marsh and Hau, 2004; Möller et al., 2009). These results suggest that very young children do not make the same clear differentiations between self-concepts that older children do.

The aforementioned findings give rise to the question of whether self-concept becomes increasingly multidimensional with age. Indeed, Shavelson et al. (1976) hypothesized that the multidimensional aspect of self-concept would increase with age. In other words, it was argued that as people get older, they become better able, and more likely, to distinguish their self-evaluations in different contexts. However, Marsh and Ayotte (2003) critiqued previous tests of this hypothesis, and found that increasing differentiation did not explain all results. Instead, Marsh and Ayotte proposed a differential distinctiveness hypothesis, which argued that with increasing age and cognitive development, there are counterbalancing processes of self-concept integration and differentiation. According to Marsh and Ayotte, integration occurs when closely related areas of self-concept (cognitive and affective components of mathematics self-concept) become amalgamated; differentiation refers to the increasing differentiation of disparate areas of self-concept (mathematics and verbal). Marsh and Ayotte supported their theoretical claims with data from young French–Canadian schoolchildren, which showed that with age dissimilar domains became more differentiated, while similar domains became more integrated, providing strong support for the differential distinctiveness hypothesis.

Researchers have also investigated how self-concept varies with age. Marsh (1989) described a curvilinear relationship between age and self-concept, whereby self-concept declines during preadolescence and early adolescence, and then levels out in middle adolescence, before increasing in late adolescence through to early adulthood. This curvilinear relationship was demonstrated by Cole et al. (2001). However, Cole et al.'s study also uncovered further complexity to the curvilinear relationship between self-concept and age. For instance, Cole and colleagues found that from middle to late childhood there were increases in academic, social, and sports competence, but an overall decrease in self-concept of behavioral conduct, and a female-only decrease in physical self-concept. At the onset of early adolescence, academic and sports self-concepts decreased significantly. Furthermore, following the transition from middle school, academic and social self-concepts recovered. Meanwhile, sports, behavior, and appearance self-concepts remained the same. Finally, the transition to high school was associated with increased self-perceived academic competence and increases in social self-concept for males and physical appearance self-concept for females. However, sports and behavioral self-concepts decreased for females at the same time. According to Cole et al., the period after the transition from high school is characterized by a plateau in self-concept scores across all five domains. This research supports Marsh's (1989) assertion that the transition from middle to high school presents the most turbulent time for self-conceptions. In addition, this time also displays more

discrepancies between male and female self-concepts than at any other time.

There are a host of theories that aim to explain the changes in self-concept that occur across the lifespan. According to Marsh and Craven (1997), children's self-concept decreases with age, as a result of increased exposure to situations that challenge high childhood self-concepts. Other researchers argue that the tumultuous transitions during puberty lead to radical decreases in self-perceptions (see Harter, 1998). Furthermore, others have posited that improved social skills, autonomy, and maturity may lead to increased self-concept (Hart et al., 1993). More research regarding the relationships between domain-specific self-concepts and age is needed to better understand the issue.

Gender Differences

Research focusing on the role of gender in self-concept has provided further support to the necessity of espousing a multidimensional model to describe self-concept. Speculation that global measures of the self are inadequate in explaining gender differences were first expressed by Wylie (1979), who argued that it was likely that gender differences in specific self-concept domains were masked by global scores of self-esteem. Instead, researchers (e.g., Dusek and Flaherty, 1981; Wylie, 1979) claimed that small differences in general self-esteem were actually reflective of counterbalancing gender differences in domain-specific self-concepts that were consistent with traditional sex stereotypes. There is a wealth of empirical evidence to support this argument. For example, in a review of gender differences in self-concept, Crain (1996) found that there was evidence of differences in domain-specific self-concepts for girls and boys that appeared to be gender stereotypic.

Other studies have further supported the notion that gender differences in self-perceptions vary across domain-specific self-concepts. Marsh's (1989) analysis of archive responses to the multidimensional SDQ instruments indicated that boys had distinctly more favorable global measures of self-concepts than their female counterparts. However, small but statistically significant, gender differences in most SDQ scales revealed that domain-specific self-concept scores typically followed sex stereotypes. For example, males had higher self-concepts in mathematics, while females fared better in measures of verbal self-concept.

This finding has been demonstrated in other studies. For example, Marsh and Ayotte (2003) replicated these findings using a French–Canadian version of the SDQ. Additionally, Lent et al. (1997) found that males exhibited higher mathematics self-concepts and higher general academic self-concepts than females. Finally, Feingold and Mazzella (1998) provided evidence for this trend in nonacademic domains of self-concepts, with the finding that male self-concepts relating to physical appearance were more positive than for their female counterparts. In summary, these studies that have analyzed gender and self-concept in a multidimensional framework are important as they provide further insight into the role gender plays in the formation of self-perceptions.

Causal Ordering of Self-Concept and Achievement: The Reciprocal Effects Model

Numerous studies have demonstrated a substantial positive correlation between academic self-concept and achievement (e.g., Marsh et al., 2006b,e). However, until recently, the causal ordering of this relation was less certain. However, this relation leaves unanswered the question of whether prior ratings of self-concept affect academic achievement, or whether academic achievement contributes to self-concept. This question is particularly important due to the theoretical and practical implications of the causal direction between these two variables. Essentially, knowing the causal ordering of self-concept and achievement is critical in determining the teaching practices that are most effective in enhancing student educational outcomes. Furthermore, answering the issue of causality is theoretically important in that much of the interest shown in self-concept stems from the belief that academic self-concept has motivational properties that contribute to achievement (Byrne, 1984).

Calysn and Kenny (1997) highlighted two opposing models relating to the causal ordering of self-concept and achievement: the self-enhancement and skill development models. The self-enhancement model posits that self-concept is a primary determinant of academic achievement and argues that interventions aiming to improve self-concept are critical in the attainment of academic success. In contrast, the skill development model argues that academic self-concept forms as a result of previous academic achievement. Thus, improving academic skills is seen as central to the enhancement of self-concept.

Until recent advances in statistical analyses, clarifying the issue of causal ordering between self-concept and academic achievement was problematic. However, the introduction of structural equation modeling into self-concept research reduced previous limitations, allowing researchers to investigate models that were theoretically and statistically more complex than the either–or arguments presented by self-enhancement and skill development models (see Marsh, 1990a; Marsh et al., 1999; Marsh and Martin, 2011). As a result of these advances, Marsh (1990a) proposed the reciprocal effects model (REM; see **Figure 1**) of academic self-concept. This model argued that the causal ordering of self-concept and achievement was not unidirectional. Instead, Marsh's model hypothesized a reciprocal relation between increases in self-concept and improvements in performance.

To test this model, Marsh (1990a) analyzed the large, nationally representative, US Youth in Transition Study. By analyzing the latent constructs of academic ability, academic self-concept, and school grades across a series of time waves, Marsh found support for a model where self-concept and achievement were reciprocally related. Marsh's study was important as it was one of the first studies that provided methodologically strong evidence for an REM, by demonstrating statistically significant pathways from prior self-concept to later achievement, and vice versa.

Cross-cultural research can inform us whether or not theories can be universally applied (Schwartz and Bilsky, 1990). Hence, the REM has been further bolstered by studies

Figure 1 Prototype causal-ordering model for testing self-enhancement, skill development, and REM. In this full-forward, multi-wave, multivariable model, multiple indicators of academic self-concept (ASC) and achievement (ACH) are collected in three successive waves (T1, T2, and T3). Each latent construct (represented by oval shape) has paths leading to all latent constructs in subsequent waves. Within each wave, academic self-concept and achievement are assumed to be correlated; in the first wave, this correlation is a covariance between two latent constructs, and in subsequent waves, it is a covariance between residual factors. Curved lines at the top and bottom of the figure reflect correlated uniquenesses between responses to the same measured variable (represented by boxes) collected on different occasions. Paths connecting the same variable on multiple occasions reflect stability (the solid gray paths), but these coefficients typically differ from the corresponding test–retest correlations (which do not include the effects of other variables). Dashed lines reflect effects of prior achievement on subsequent self-concept, whereas solid black lines reflect the effects of prior self-concept on subsequent achievement. Adapted with permission from Marsh, H.W., 2007. Self-concept Theory, Measurement and Research into Practice: The Role of Self-concept in Educational Psychology. British Psychological Society, Leicester, UK.

demonstrating good cross-cultural generalizability. Support for the REM in studies has come from different countries, for example, Hong Kong (Marsh et al., 2002b), Belgium (Pinxten et al., 2014), Germany (Marsh et al., 2001a, 2005b), and Canada (Guay et al., 2003).

Further strengthening the claims of the REM, evidence for reciprocal relations between self-concept and performance has been found outside the classroom. Marsh et al. (2006c) demonstrated the REM in a study investigating the causal ordering of physical self-concept and exercise behavior. Furthermore, Marsh et al. (2006a) tested the reciprocal effects, self-enhancement, and skill development models in relation to the physical self-concept and performance of gymnasts, and again found support for an REM of self-concept and performance. These findings are further supported by Marsh and Perry's (2005) study of self-concept and performance in a sample of elite swimmers in which prior self-concept was a significant positive predictor of subsequent championship performance.

Challenges to the REM

The REM provides evidence for the positive psychology movement. At the core of this movement is the belief that positive conceptions of the self are associated with enhanced life outcomes. Baumeister et al. (2003) challenged this premise in an influential review commissioned for Psychological Science in the Public Interest, arguing "that efforts to boost people's self-esteem are of little value in fostering academic achievement or preventing undesirable behavior" (p. 84).

However, in the context of recent advances in methodological and theoretical understandings of self-concept, Baumeister et al.'s (2003) conclusions are problematic. In particular, Baumeister et al. relied on a unidimensional perspective that emphasized self-esteem, largely ignoring research based on a multidimensional perspective reviewed here that focused on academic self-concept. From a multidimensional perspective it is reasonable that esteem has little or no relation with academic achievement even though academic self-concept and achievement are reciprocally related (Marsh and Craven, 2006). Marsh and O'Mara (2008) subsequently provided clear support for this theoretical claim, juxtaposing the negligible effects of self-esteem with the substantial effects of academic self-concept in a reanalysis of the classic Youth in Transition study highlighted by Baumeister et al. (in relation to self-esteem) and by Marsh and Craven (in relation to academic self-concept). This conclusion is also consistent with the meta-analytic research which found consistent support for a reciprocal relation between academic self-concept and achievement, but little to no reciprocal effect between achievement and self-esteem (Valentine and DuBois, 2005; Valentine et al., 2004).

In summary, the REM has been a critical development in self-concept theory. Firstly, the model established that positive self-concept and achievement are mutually reinforcing. Secondly, this finding supports the notion that positive self-concept is an integral part of success and achievement. Finally, these findings have important implications for educators. That is, since self-concept and achievement are mutually reinforcing and reciprocally related, interventions aimed at improving performance should not only strive to promote skill development, but also seek to simultaneously enhance self-concept to encourage achievement.

Frames of Reference Models

Since William James (1890), psychologists have stressed that self-concept cannot be understood without recognizing the role that comparative processes play in perceptions of the self. Essentially, while people may share the same objective characteristics or accomplishments, differing frames of references or standards of comparisons can lead to disparate self-concepts among individuals.

Social Comparison and the Big-Fish–Little-Pond Effect

Integrating research based on a variety of theoretical models and empirical studies (e.g., Davis, 1966; Festinger, 1954), Marsh (1984; also see Marsh et al., 2008) proposed the

big-fish–little-pond effect (BFLPE; see Figure 2) that is specific to educational settings. According to the BFLPE, students compare their own academic abilities with the abilities of their classmates, and use this social comparison as the basis of their academic self-concept. In the BFLPE, students who attend high-ability classes and schools tend to have lower academic self-concepts than equally able students who attend mixed- or low-ability classes and schools. Thus, the BFLPE explains how students with equal ability can have differing academic self-concepts as a result of the educational settings they attend.

Since the initial BFLPE study (Marsh and Parker, 1984), there has been a wealth of support for BFLPE predictions based on studies that use differing experimental and analytical approaches (Marsh, 1987; Marsh and Craven, 1994, 1997; see review by Marsh et al., 2008). Furthermore, Marsh (1991) demonstrated that students attending higher-ability high schools were likely to not only suffer from depleted academic self-concepts, but were also likely to have lower GPAs, lower educational aspirations, lower occupational aspirations, lower standardized test scores, and were also more likely to select less demanding coursework than their equally abled peers attending schools with lower average abilities. These findings are significant as they have important implications for parents, teachers, and policy makers, as they dispute the common held belief that it is advantageous to send students to schools with stellar academic reputations. Instead, Marsh argues that the findings of BFLPE indicate that many students attending high-average schools are not reaching their full academic potential.

Further support for the BFLPE was also found in the quasi-experimental setting that occurred after the fall of the Berlin Wall (Marsh et al., 2001a). Essentially, the fall provided researchers the opportunity to compare the effects of attending school systems that differed in the extent that they segregated students by ability. While West German students had previously attended academically differentiated schools, East German students had not been exposed to an academically differentiated school system. Results of the study supported the BFLPE predictions. The BFLPE was significantly larger for West German students at the start of reunification of the schooling systems. Importantly, as time passed the difference in the size of the effect between East and German students was reduced, and eventually disappeared after the East German students had been exposed to the West German schooling system for a year. According to Marsh, Köller, et al. these findings are a testament to how national educational policy differences impact upon the academic self-concepts of individual students.

Figure 2 Big-fish–little-pond effect. Reproduced from Marsh, H.W., Hau, K.T., 2003. Big-fish–little-pond effect on academic self-concept: a cross-cultural (26 country) test of the negative effects of academically selective schools. American Psychologist, 58, 364.

In research reviewed by Marsh et al. (2008), there is consistent cross-cultural support for the BFLPE based on studies from many different countries. Demonstrating that the BFLPE is one of psychology's most cross-culturally universal phenomenon, three successive Program for International Student Assessment (PISA) data collections (Marsh and Hau, 2003; 103 558 students from 26 countries; Seaton et al., 2009, 2010; 265 180 students from 41 countries; Nagengast and Marsh, 2012; 397 500 students from 57 countries) showed that the effect of school-average ACH on ASC was negative in all but one of the 123 samples and significantly so in 114 samples.

Seaton et al. (2010) evaluated whether the BFLPE was moderated by 17 individual student characteristics (student background, learning styles, and the perceived learning environment) based on the large PISA 2003 database. However, they concluded "that the BFLPE was an extremely robust effect" (p. 390). Jonkmann et al. (2012) evaluated whether the BFLPE was moderated by personality factors (big-five traits and narcissism). They found that students high in narcissism had exaggerated academic self-concept and smaller BFLPEs. In contrast, students high in neuroticism experienced more negative BFLPEs. However, these moderation effects were modest in that they did not change the direct of the BFLPE, again supporting the robustness of the BFLPE.

While most BFLPE studies use high school student samples, the effect has been demonstrated in primary school' gifted and talented classes (Marsh et al., 1995). Therefore, the assumed benefits of gifted and talented programs are also called into question by the BFLPE. In addition to this, the BFLPE has found support among academically disadvantaged students placed in mainstream classes (Tracey et al., 2003; Marsh et al., 2006d). The findings of these studies were in contrast to labeling theory, which predicts that placement of academically disadvantaged children in special classes will lead to lower self-concepts and stigmatization. Instead, results indicated that academically disadvantaged students placed in regular classes in fact had lower self-concepts than their equally able peers who were grouped in classes with other students of similar abilities. These findings are important as they indicate that the very policies aiming to include students are at the same time having detrimental effects on students' academic self-concept.

Dimensional Comparisons and the I/E Model

Researchers have also brought attention to the role that internal comparisons play in shaping self-concept. For example, Albert (1977) proposed that individuals also undertake temporal comparisons in order to form self-evaluations. Temporal comparisons are performed within an internal frame of reference, whereby individuals compare themselves across time. Furthermore, Möller and Marsh (2013) described another internal comparative process known as dimensional

comparison, whereby individuals compare their own abilities in one area to another. For example, a student may ask, "How good am I in mathematics compared to English?"

These dimensional comparisons are the focus of the 'Classic' Internal/External Frame of Reference (I/E) model, which investigates the association between academic self-concept and achievement. In accordance with the hierarchical aspect of self-concept, correlations between mathematics and verbal self-concepts are typically weak or even negative (Marsh, 1986; see **Figure 3**). Furthermore, Marsh demonstrated that pathways between domain-specific achievement and the corresponding self-concept were substantial and positive. In contrast, paths from mathematics achievement to verbal self-concept and vice versa were significant and negative. Essentially, people tend to see themselves as either a mathematics or a verbal person, but rarely both. What makes this finding interesting is that although mathematics and verbal self-concepts are uncorrelated, objective measures of academic performance indicate that mathematics and verbal abilities are usually similar (Marsh, 1986). Therefore, there is a paradoxical relationship that exists between academic self-concepts and their corresponding measures of academic performance.

The I/E model was developed to explain the aforementioned paradoxical relationship between subject-specific self-concepts and achievement (Marsh, 1986). Marsh argues that academic self-concepts in particular school subjects are formed through, not only external references, but also internal references such as dimensional comparisons. These occur when students compare their own performance in one subject to their own performance in another school subject. According to the model, good verbal skills lead to lower mathematics self-concept as a result of these dimensional comparison processes, and vice versa.

The I/E model has been widely supported across a number of studies differing in sample nationality, age, and in the uses of self-concept and measures of achievement (see Marsh, 1990b; Marsh and Craven, 1997). Meta-analyses have demonstrated further support for the model, again showing

Figure 3 The 'Classic' Internal/External Frame of Reference (I/E) Model relating verbal and mathematical achievement to verbal and mathematical self-concepts. According to predictions from the I/E model, the horizontal paths from achievement to self-concept in the matching domain (content area) are predicted to be substantial and positive (++), whereas the cross paths from achievement in one domain area to self-concept in a non-matching domain (shaded in gray above) are predicted to be negative (−).

generalizability across age, gender, and nationality (Möller et al., 2009; Marsh and Hau, 2004). There has also been experimental research that has enabled confirmation of the causal hypotheses of the I/E model (Möller and Köller, 2001). In this study Möller and Köller were able to demonstrate that manipulation of feedback on achievement in one subject area had an inverse effect on self-concept in the subject at the opposite end of the verbal–mathematics continuum. Furthermore, diary studies have also confirmed that students spontaneously undertake dimensional comparisons on a day-to-day basis. Importantly, these dimensional comparisons have been shown to predict post-school education and career pathways (Parker et al., 2012; Parker et al., in pressa,b).

The I/E model has been an important development in self-concept theory as it highlighted the hierarchical aspect of self-concept, leading to the Marsh/Shavelson revision of the original Shavelson model of self-concept. This theoretical development has been important in the practice of educational psychology, as it has highlighted the fact that even academic self-concept is highly domain specific. This means that psychologists should take careful consideration of the way they choose to measure academic self-concept to ensure that the level of specificity is appropriate to research aims and intervention goals.

Personality and Self-Concept

Personality researchers make a distinction between core personality traits such as the Big Five (neuroticism, extraversion, conscientiousness, agreeableness, and openness) and self-concept, which they perceive to be a more malleable personality characteristic. Although both self-concept and personality researchers agree that their constructs should be viewed from a multidimensional perspective, Marsh et al. (2006e; see also Marsh, 2008) noted that personality researchers have relied heavily on global self-esteem measures rather than on multidimensional self-concept measures that are more commonly used by self-concept researchers. Moreover, these authors noted that there is a paucity of research combining personality and self-concept from a multidimensional perspective.

Research that has examined personality and global self-esteem has shown that the latter to be negatively related to neuroticism (Judge et al., 1998; also see Francis and James, 1996; Furr and Funder, 1998; Watson et al., 2002) and somewhat less positively related to extraversion (e.g., Francis and James, 1996; Furr and Funder, 1998; Watson et al., 2002). The few studies that have examined relations between self-esteem and the complete set of Big Five factors have found positive correlations between self-esteem and conscientiousness, openness, and agreeableness (see Watson et al., 2002).

In response to the limited amount of studies relating multidimensional personality factors with multidimensional self-concept factors, Marsh et al. (2006e) evaluated relations between 17 clearly defined self-concept factors (extended SDQIII), personality (Big Five), well-being (positive and negative affect and life satisfaction), and academic outcomes

(school grades, test scores, and coursework selection) in young adult students (17–19 years). They found that substantial amounts of variance in each of the Big Five and well-being factors could be explained by specific self-concept factors, varying between 23% and 60% (M = 39%) for the Big Five factors and between 14% and 19% (M = 17%) for the well-being factors. Quite the reverse was found for self-esteem; almost none of the variance in any of the Big Five or the well-being factors could be uniquely explained by self-esteem. That the pattern of relations between self-concept and personality factors was so highly differentiated and multivariate suggests that personality researchers should consider using multidimensional self-concept measures in place of the commonly used unidimensional ones.

Marsh et al. (2006e) found support for convergent validity (self-concept and personality factors that were logically related were substantially correlated) and divergent validity (self-concept and personality factors that were not logically related were not substantially related), most especially in seven higher-order factors encompassing both self-concept and personality factors. Moreover, personality was confirmed as a multidimensional construct, as each Big Five personality factor loaded primarily on one and only one of the seven higher-order factors. Furthermore, specific self-concept components and Big Five personality factors that one would logically associate with each other loaded on the same higher-order factor. Moreover, two higher-order factors (reflecting the quantitative-academic components of self-concept and religious self-concept) were relatively unrelated to all personality factors. Self-esteem relations confirmed the multidimensional nature of self-concept. Not only did self-esteem load on just one of the seven higher-order factors, but also was not even the highest loading of all the self-concept factors. Further demonstrating the multidimensional perspective of self-concept, the association between self-esteem and each of the nine nonacademic outcome measures was modest (rs varied from −0.03 to 0.05). Conversely, the relations between academic outcomes and the academic components of self-concept were highly differentiated and substantial. It is interesting to note that there was only a moderate association between the Big Five personality and well-being factors and the academic outcomes. Moreover, these personality constructs were unable to additionally contribute to the prediction of the academic outcomes over and above that which could be explained by the academic components of self-concept.

In summary, Marsh et al. (2006e) have provided both personality and self-concept research with a way forward by demonstrating how multidimensional personality constructs and multidimensional self-concept constructs relate to each other. In doing so, they have begun the process of integrating two very important and productive strands of social psychology.

Summary

The self-concept construct has had a long and distinguished history. Although once conceptualized as unidimensional, research over the last 35 years has demonstrated that self-concept is indeed a multidimensional construct. As Marsh and Hattie (1996) aptly declared, "there appears to be no support at all for the unidimensional perspective of self-concept or, apparently, even a unidimensional perspective of academic self-concept" (p. 44). Indeed, self-concept research has blossomed in this period, spanning issues as varied as developmental perspectives, to gender differences, effects of differing frames of reference on self-concept, self-concept's association with personality, and the reciprocal relation that it has with achievement. These advances in self-concept are exciting and augur well for the future of the discipline. Perhaps more importantly they demonstrate how crucial a positive self-concept is in many areas of human functioning and endorse Marsh and Craven's (2006) description of self-concept as a "hot variable that makes good things happen, facilitating the realization of full human potential in a range of settings" (p. 134).

Self-Concepts: Educational Aspects

Reinhard Pekrun and Elizabeth J Stephens, University of Munich, Munich, Germany

Abstract

Self-concepts are beliefs people hold about themselves. They are stored in memory, can be organized in hierarchical ways, and can pertain both to real attributes of the self and to nonfactual (e.g., ideal) aspects of the self. Findings of educational self-concept research show that students' self-concepts are largely organized according to academic domains (e.g., verbal vs math academic self-concept). They are reciprocally linked to academic achievement, implying that achievement results underlie the formation of related self-concepts, and that self-concepts in turn influence motivation, learning, and achievement. Beyond academic self-concepts, education at home and in academic institutions also influences students' general self-esteem. Important educational factors affecting general self-esteem as well as more specific self-concepts are acceptance by significant others (e.g., parents and teachers), consistent behavioral rules, support of autonomy, academic instruction, and feedback on abilities, behavior, and achievement. Of specific importance are reference norms used for giving feedback (e.g., social comparison vs mastery-oriented norms).

The capacity to reflect on one's capabilities and actions is uniquely human. Early in life, young children begin to form beliefs about the self that help them interpret the world and themselves, and serve as frames of reference for regulating emotion, motivation, and behavior. Research on self-related beliefs can be traced back to the seminal writings of William James (1893) who distinguished the self as 'I' ('existential self') and as 'me' ('categorical self'). The latter involves cognitions about the self as an object of reflection, as represented in statements such as 'I am thinking about me.' During the first half of the twentieth century, research on self-concepts was slow to develop. However, in the 1960s and 1970s, once behaviorist approaches were gradually replaced by cognitive accounts of psychological processes, psychologists started to recognize the importance of self-related cognitions for human agency. At that time, the self-concept construct gained a central status in psychology and applied fields like educational research. Subsequently, the number of studies on self-concepts increased dramatically. Today, we have cumulative knowledge about the structures, origins, and functions of self-concepts, including their role in education (Bracken, 1996; Valentine et al., 2004; Marsh et al., 2008).

Conceptual Issues

The term 'self-concept' is used in two ways. Talking about *the* self-concept of an individual should be distinguished from referring to a number of *different* self-concepts within the individual. 'The' self-concept is the whole of an individual's cognitive representations of him- or herself that are stored in memory. Different self-concepts are subsets of such representations that relate to different attributes of the self, such as cognitive abilities, physical appearance, or social status. Both variants of the term imply that self-concepts are self-representations that are more or less enduring over time, in contrast to situational, momentary self-perceptions that can vanish when the situation is over. The definition is open to whether these representations refer to actual personal attributes, such as real abilities, or to fictitious (e.g., possible or ideal) attributes.

There are two conceptual problems with the term 'self-concept' that are not adequately solved to date. First, it remains unclear whether self-related emotions such as pride or shame should be included or not. On the one hand, it can be argued that emotions are different from cognition, and that self-concepts should be defined as (purely) cognitive constructs. From this perspective, (cognitive) self-concepts and (emotional) self-related feelings can be combined using umbrella terms such as *self-esteem*, but should be considered as distinct entities in the first place. This perspective is supported by research showing that cognitive and affective components of self-concept scales can be separated empirically (e.g., Arens et al., 2011). On the other hand, many measures of self-concepts combine cognitive and affective items reflecting self-evaluation, which implies using a more integrative perspective. An important example is H. Marsh's widely used Self-description Questionnaire (Marsh, 1988) which includes both cognitive items (e.g., 'I am good at mathematics') and affective items (e.g., 'I enjoy doing work in mathematics') to measure self-concepts.

Second, there is insufficient agreement about the conceptual overlap between self-concept and other types of self-related cognitions. Specifically, what about cognitions linking the self to one's actions and the environment – are these cognitions part of self-concept or not? Two examples are self-efficacy beliefs and beliefs about personal control (Skinner, 1996). Self-efficacy beliefs pertain to one's capabilities to successfully solve specific tasks, thus linking self-attributes (ability) to actions (task performance) and environmental demands (a domain of tasks; Pajares, 1996). Beliefs about personal control, or 'perceived control' (Perry, 2003; Skinner, 1996), pertain to expectancies that one's actions produce desired outcomes. Given that these beliefs include representations of the self (along with other components), it could be argued that they should be considered as part of an individual's self-concept. However, self-concept, self-efficacy, and perceived control are viewed as separate constructs by most researchers and have been addressed in distinct research traditions up to date.

Types and Structures of Self-Concepts

Different types of self-concepts relate to different attributes of the self, such as one's abilities versus one's physical appearance. In addition, self-concepts can be of a more descriptive or more evaluative nature, and can pertain to either the factual reality of these attributes ('real self') or to fictitious attributes (e.g., one's 'ideal self'). Moreover, self-concepts can be explicit or implicit. As yet, educational research has primarily focused on examining structures of students' explicit concepts of the real self. Most of these studies targeted students' academic self-concepts representing their cognitive abilities.

Hierarchies of Self-Concepts and Attributes

Self-concepts pertaining to different attributes can be conceptualized in hierarchical ways, similar to semantic memory networks. From such a perspective, more general self-concepts are located at higher levels of the hierarchy and specific self-concepts at lower levels. In educational research, the hierarchical self-concept model proposed by Shavelson et al. (1976) stimulated an abundant number of studies on the structure of students' self-concepts. In this model, a 'general self-concept' is located at the top of the hierarchy. The next level includes an 'academic self-concept' representing one's academic abilities, as well as social, emotional, and physical nonacademic self-concepts. Self-concepts pertaining to different academic domains and to social, emotional, and physical subdomains are located on the third level, and even more specific self-concepts involving representations of situation-specific behavior on lower levels.

Research has shown that the correlations between academic self-concepts pertaining to different academic domains, such as math versus verbal self-concept, tend to be zero, in contrast to students' academic performance which is typically correlated positively across academic domains. Specifically, zero correlations are found for self-concepts across dissimilar domains, such as mathematics and English (Marsh and Shavelson, 1985). Moreover, affective variables that are likely to depend on students' self-concepts, including students' interests, values, goals, and academic emotions, have also been found to be organized in domain-specific ways (i.e., correlations are low to zero across domains; Bong, 2001; Goetz et al., 2007).

How can we explain the domain specificity of academic self-concepts and related variables? A theoretical account is provided by Marsh's (1986) Internal/External Frame of Reference model (I/E model). This model posits that students' academic self-concepts are based on comparisons using two types of standards: an internal, within-individual standard of comparing one's performance across academic domains (e.g., 'How does my performance in math compare to my performance in English?') and an external, between-individuals standard comparing one's performance with the performance of other students (e.g., 'How does my performance in math compare to other students' performance in math?').

Use of internal standards should lead to negative correlations between different academic self-concepts (e.g., perceiving high ability in math should lead to reduced estimates for verbal ability, and vice versa). In contrast, use of external standards based on social comparison should lead to positive correlations across domains, because performance scores and one's relative achievement status within a class are positively correlated across academic domains (e.g., positive correlations between math and verbal scores). The model proposes that students use both types of standards, implying that opposing effects can cancel each other out and that the overall correlations can be zero across domains. Given the domain specificity of academic self-concepts, researchers also have proposed modifying the original Shavelson et al. (1976) hierarchical model by including math and verbal self-concepts and omitting general academic self-concept (Marsh and Shavelson, 1985).

Different Perspectives on Attributes

Self-representations can consist of descriptive and evaluative accounts of attributes (e.g., 'I am tall' vs. 'I am an attractive person'). In academic self-concepts, this distinction is blurred because the use of comparative performance standards leads to judgments that involve an amalgam of descriptive and evaluative components (e.g., the statement 'I am better in English than most of my classmates' both describes and evaluates the self).

In forming self-concepts, one can use the same types of standards that teachers use to evaluate academic achievement and students use to develop their achievement goals (Elliot et al., 2011). These standards include (1) social comparison across individuals (external frame of reference in Marsh's I/E model cited earlier); (2) intraindividual comparison of present performance with past performance (i.e., improvement vs deterioration); (3) intraindividual comparison of actual performance with one's ability (i.e., potential performance); (4) intraindividual comparison of performance across domains (internal frame of reference in Marsh's I/E model cited earlier); (5) task-oriented comparison of one's performance with task mastery standards; and (6) cooperative standards linking individual performance to group performance.

Beyond existing attributes ('real self'), self-representations can pertain to attributes of the self that do not actually exist, but might exist ('possible selves'), are desired by oneself ('ideal self'), are wanted by others ('ought self'; Higgins, 1987), etc. Concepts of nonreal selves can also be important for students' affect and motivation. For example, discrepancies between real and ideal self are thought to trigger depressive emotions, whereas discrepancies between real and ought self can induce anxiety (Higgins, 1987).

Explicit versus Implicit Self-Concepts

Similar to other variables that involve human affect and behavior (e.g., motives; Schultheiss, 2008), not only can self-concepts be explicit, reflective, and deliberate, but they can also be implicit and nonreflective. Explicit self-concepts consist of propositional structures that result from deliberate information processing. These self-concepts can be described by models capturing reflective, propositional associations between the self and its various attributes, such as the hierarchical Shavelson et al. (1976) model discussed earlier. In contrast, implicit self-concepts are thought to be based on associative structures that result from automatic information

processing involving spontaneous associations between the self and an attribute rather than any deliberate cognitive effort. Explicit self-concepts can be assessed using self-report methods such as questionnaires and interviews, whereas assessment of implicit self-concepts needs indirect methods to assess associations that are less accessible to the conscious mind, such as the Implicit Association Test (e.g., Greenwald and Farnham, 2000).

To date, educational research has focused on analyzing students' and teachers' explicit self-concepts, and has only just begun to examine the structures and functional role of implicit self-concepts. Initial findings on these self-concepts suggest that they can play a major role in students' motivation and performance. For example, recent studies found that discrepancies between students' explicit and implicit self-concept of general cognitive ability (i.e., intelligence) predicted decreased performance on intelligence tests (Dislich et al., 2011). It seems likely that implicit self-concepts are as important for students' academic agency as implicit motives have been found to be.

Self-Concepts and Academic Achievement

The link between self-related beliefs and achievement is one of the most frequently examined research questions in the social sciences. The relationship between students' self-concepts and academic performance also has been analyzed in several hundreds of studies. In the first phase of research, researchers examined this relationship by using cross-sectional designs and correlating self-concepts scores with performance scores. Later, longitudinal designs were employed to investigate predictive effects of prior self-concepts on subsequent achievement and to investigate reciprocal effects linking the two constructs over time.

Empirical Evidence

The evidence from cross-sectional studies shows that self-concepts and students' achievement are positively correlated. However, the magnitude of the correlation depends on the self-concept and achievement measures used. Academic self-concepts show higher correlations with academic performance than general self-concept or general self-esteem, in line with principles of symmetry and compatibility (Brunswick, 1955; Fishbein and Ajzen, 2010). In a meta-analysis by Hansford and Hattie (1982), the average correlation between students' general self-esteem and achievement was $r = 0.22$, whereas the correlation between students' academic self-concept and achievement was $r = 0.42$. When both self-concepts and achievement are assessed in more domain-specific ways (e.g., math self-concept and math achievement), the correlations tend to be even higher. This pattern of findings suggests that the link between self-concept and achievement is fortified when the measures for both constructs are conceptualized in domain-specific ways.

Beyond cross-sectional correlation, longitudinal studies have shown that self-concept is a positive predictor of subsequent academic achievement, even when controlling for baseline achievement scores. Valentine et al. (2004) conducted a meta-analysis of 55 research reports on the predictive achievement effects of various self-beliefs. The average Betas for the effects of self-concept, self-esteem, and self-efficacy on achievement when controlling for baseline achievement were 0.08, 0.07, and 0.11, respectively. These findings suggest that students' self-concepts do have a positive causal impact on achievement, in contrast to views positing that self-beliefs do not affect achievement or even undermine it (see Baumeister et al., 2003; Marsh and Craven, 2006).

Finally, using cross-lagged analysis and structural equation modeling of longitudinal data, researchers can simultaneously examine the effects of self-concept on subsequent achievement and of achievement on subsequent self-concept scores. Specifically, cross-lagged designs are well-suited to more fully examine the causal effects underlying self-concept/achievement correlations. Competing theoretical perspectives on these effects were proposed by the 'skill development model' maintaining that students' self-concepts result from prior experiences with academic achievement (i.e., effects of achievement on self-concept), and the 'self-enhancement approach' positing that self-concept influences achievement (Helmke and van Aken, 1995). Both perspectives are combined in models acknowledging reciprocal causation, such as the reciprocal effects model (REM) proposed by H. Marsh and his colleagues (see Marsh and Craven, 2006).

The findings from cross-lagged studies lend credence to the validity of the REM (e.g., Marsh et al., 2005). Typically, the effects of achievement scores on subsequent self-concept are somewhat stronger than the effects of self-concept on subsequent achievement. Overall, the evidence indicates that students' self-concepts positively influence their achievement, and that achievement, in turn, has positive effects on the development of students' self-concepts. Less is known about the mechanisms producing these effects, however. The next section highlights some potential mediating processes.

Effects of Self-Concept on Achievement

It seems unlikely that beliefs about one's capabilities directly affect subsequent performance - there must be mechanisms mediating these effects. Two important possible mechanisms are motivation for self-consistency and the effects of self-concepts on perceived academic control and achievement expectancies. In terms of *self-consistency*, humans seek to maintain consistency between their self-views and behaviors (Swann, 1997). By implication, students who hold positive views of their academic abilities should strive to attain success in order to be consistent with their self-view, whereas students with lower academic self-concepts may be motivated to behave in accordance with a more pessimistic self-view. Such self-consistent behavior would lead to performance scores that are consistent with students' self-concepts, thus supporting the positive correlation between self-concept and achievement.

With regard to *perceived control* and *achievement expectancies*, perceptions of one's abilities should be a major source of perceived control over achievement and related expectancies to attain success and to avoid failure. By implication, academic self-concepts should influence affective processes that depend on control appraisals and expectancies. Specifically, from the perspective of expectancy-value theories of student motivation (Eccles and Wigfield, 2002), academic self-concepts have positive effects on students' expectancies to succeed, thus

positively influencing their motivation to learn and ultimately their achievement. Similarly, from the perspective of the control-value of achievement emotions (Pekrun, 2006), academic self-concepts should have a positive impact on students' perceived control over achievement, thus increasing adaptive emotions such as enjoyment of learning and hope for success, and reducing maladaptive emotions such as anxiety, hopelessness, and boredom. Since these emotions affect students' learning, they are likely to mediate the effects of academic self-concepts on students' achievement (see e.g., Pekrun et al., 2011, for related evidence).

Effects of Achievement on Self-Concepts

Success and failure are likely to be a major source of students' academic self-concepts. Specifically, if achievement is made salient (e.g., in terms of feedback by teachers), and if successful or unsuccessful achievement experiences are repeated in cumulative, consistent ways over time, it is likely that students self-concepts of ability develop congruently with their academic performance attainment (see next section). This would explain the positive impact of achievement scores on students' academic self-concepts. Moreover, in contrast to the more complicated mechanisms mediating effects of self-concept of achievement, the effects of achievement on self-concept formation are more straightforward in terms of involving a smaller number of mediating variables. This might help to explain why the effects of achievement on self-concept are typically stronger than the effects of self-concept on achievement.

Development of Self-Concepts

Human Needs Underlying Self-Concept Development

Two categories of basic human needs are thought to govern the development of self-representations (Epstein, 1973). The first category includes needs for maximizing pleasure and minimizing pain, from which stem needs for self-enhancement. Because it is pleasurable to maintain a positive view of the self and painful to maintain a negative view, humans should generally be motivated to establish positive self-perceptions (even if they do not coincide with reality). The second category comprises needs to understand reality and foresee the future, which implies the need to maintain self-perceptions that are in and of themselves consistent as well as consistent with reality (i.e., needs for consistency). Self-enhancement and consistency converge when feedback about the self is positive; however, they can conflict when feedback is negative. Furthermore, satisfying needs for self-enhancement may lead an individual to reject negative feedback, whereas satisfying needs for consistency with reality may result in the individual endorsing such feedback if it is deemed veridical. The development of students' self-concepts can be explained by the interplay of these partially opposing needs systems.

Developmental Trajectories across the Life Span

In line with needs for self-enhancement, if information about real abilities lacks salience or is unavailable, then humans tend to overestimate their capabilities. At the same time, they search for factual information about the self and can even be motivated to endorse negative self-information if it is salient and consistent. In accord with these opposing trends, studies have shown that many children dramatically overestimate their academic abilities upon entering school, but over time lower their self-evaluations when teachers' feedback repeatedly diverges from such positive self-views (Nicholls, 1978). Young children's lack of metacognitive competencies may make it difficult for them to use feedback to develop realistic perceptions of their abilities; however, this process can be expedited later. As a general rule, the interplay between beginner's optimism and expert's realism is likely to extend beyond the elementary school years and emerge in numerous situations such as starting college, entering a new career, and getting married (Perry, 2003). Indeed it can be said that self-concept development over much of the life span is characterized by this joint action between the sometimes opposing forces of self-related optimism and realism.

Impact of Educational Environments

The influence of social environments was addressed early in the twentieth century by symbolic interactionism, which posited that interactions with significant others shape the development of self-concepts (cf. the concept of the 'looking glass self'; Cooley, 1902). The environment provides various sources of self-related information and such information can influence students' self-concepts, including attributions of ability and personal worth, opportunities to develop and demonstrate knowledge and competencies, achievement feedback, and the composition of student groups and related opportunities for social comparison of one's abilities.

First, the *attributions* teachers, parents, and peers provide for success and failure (e.g., attributions to ability vs. effort) influence students' self-concepts. These attributions can be conveyed directly, for example, in verbal messages (e.g., 'You failed the exam because you didn't prepare well'). Additionally, attributions from others can take more indirect forms, such as the implied messages communicated by others' emotional and instrumental behavior. Importantly, these oftentimes well-intentioned messages can produce contradictory effects, such as help from a teacher on an easy task or praise for successful performance on an easy task indicating low ability (paradoxical effects of praise; e.g., Rheinberg, 1988). Messages about personal worth can also be conveyed indirectly, for example, by teachers showing student support and expressing affection and positive emotions. These messages and attributions are of fundamental importance for the development of students' general self-esteem (e.g., Pekrun, 1990).

Second, learning environments provide *learning opportunities* that help build the knowledge and skills that make it possible for students to attain success and develop positive academic self-concepts. Specifically, high-quality classroom instruction can promote successful student learning and related self-concepts (Hattie, 2009). Furthermore, environments supportive of autonomy can help students acquire important self-regulatory abilities that enable them to effectively guide and manage their own learning. Finally, consistent behavioral rules can enhance the cognitive predictability of students'

environments which can also positively affect their overall sense of competence.

Third, *achievement feedback* is likely critical for self-concept development. As noted earlier, feedback that is salient, consistent across situations, and cumulative over time may be especially relevant to students' self-concepts. The content of and achievement standards used for feedback are important as well. Specifically, as noted earlier, different definitions of achievement are provided by normative, intraindividual, task-referenced, and cooperative standards (Elliot et al., 2011; Johnson and Johnson, 1974). Normative standards (i.e., social comparison standards) are competitive and define achievement in relation to one's peers (i.e., high achievement implies outperforming peers, low achievement implies performing worse than one's peers). Intraindividual standards define achievement in terms of individual improvement over time or in terms of using one's potential. In task-oriented (criterion-referenced) standards, achievement is defined in terms of attaining mastery of the learning material. Cooperative standards define achievement in terms of group performance rather than individual performance.

Because these different standards imply differential opportunities for students to experience success, they also affect students' self-concepts. Specifically, in contrast to criterion-referenced and intraindividual standards, normative standards imply that some students can attain success, whereas others must fail. The failure experiences produced by normative standards and competitive grading structures can, for some students, contribute to lowered academic self-concepts.

Finally, the *composition of student groups* influences students' within-group achievement position, thus also affecting their self-concepts of ability. Specifically, the ability levels of student groups determine students' opportunities to experience success and avoid failure, thereby impacting self-concepts. All things being equal, membership in a high-ability classroom reduces one's chances to succeed relative to others, whereas membership in a low-ability classroom increases the likelihood of attaining success. Two opposing types of social comparison processes are thought to mediate the impact of group-level ability on students' self-concepts: *Contrast effects* focus one's attention on differences between oneself and the group, implying that self-concepts of ability are reduced if individual achievement is low relative to the group, and increased if achievement is high relative to the group. *Assimilation effects* imply adapting self-concepts according to group membership, thus increasing self-concepts for members of high-ability groups and decreasing self-concepts for members of low-ability groups.

Contrast and assimilation effects on academic self-concepts have been called the *big-fish-little-pond effect* (BFLPE) and the *reflected-glory effect*, respectively (Marsh, 1987; Marsh et al., 2000). Research has shown that the BFLPE on students' academic self-concepts is usually stronger than reflected glory effects. By implication, membership in high-ability classrooms typically has negative effects on students' average academic self-concepts, whereas membership in low-ability classrooms has positive effects. The BFLPE is known to be one of the most robust effects in the social sciences and has been shown to occur in students of various age groups and in various educational institutions around the globe (Marsh et al., 2008). One of the paradoxical implications of this effect is that students' self-concepts tend to decrease after transitions to high-ability school tracks and classrooms (such as classes for gifted students), and tend to increase after transitioning to a lower-ability classroom.

Summary of Implications for Educational Practice

Fostering students' self-concepts can be beneficial for their academic performance, career trajectories, and personality development. Furthermore, since positive self-regard is a key component of psychological health and well-being, nurturing students' self-concepts is an educational goal that is in itself valuable. From the evidence cited earlier, it follows that education can contribute substantially to self-concept development. Acceptance and support in educational environments such as schools and the family are important for students' general self-esteem. In addition, providing students with positive, specific feedback about their individual strengths in terms of performance, abilities, and personality can help them develop optimistic self-concepts and life expectancies. In designing feedback, it is helpful to define achievement using criterion-referenced, individual, or cooperative standards rather than to rely on competitive standards and normative grading. Moreover, educators can promote students' self-concept development by providing high-quality instruction, establishing consistent, predictable expectations of behavior, and supporting autonomy and self-regulation in order to promote students' perceptions of control and competence.

Selfconscious Emotions, Psychology of

June P Tangney, George Mason University, Fairfax, VA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Shame, guilt, embarrassment, and pride are 'self-conscious emotions,' evoked by self-reflection and self-evaluation. A growing empirical literature indicates that shame and guilt are distinct emotions with very different implications for psychological adjustment and interpersonal behavior. In brief, shame involves a negative evaluation of the global self, whereas guilt involves a negative evaluation of a specific behavior. On balance, guilt appears to be the more adaptive emotion, benefiting relationships in a variety of ways. Shame has been associated with a variety of negative outcomes – evasion, denial, anger, and vulnerability to a range of psychological symptoms. Recent research, however, has begun to explore the conditions under which shame may be adaptive – fostering meaningful change. Embarrassment is not simply a mild form of shame, but is marked by more humor, more obvious physiological changes (e.g., blushing), and a greater sense of exposure. The diversity of situations that cause embarrassment makes a comprehensive 'account' of embarrassment difficult. There is greater consensus about its adaptive significance. Embarrassment signals appeasement to others, thus diffusing negative social evaluations and the likelihood of retaliation. In recent years, pride has received long overdue attention. Paralleling the self versus behavior distinction central to shame and guilt, there are two types of pride. The propensity to experience pride about behavior ('authentic' or 'behavioral' pride) appears to be similarly more adaptive than the propensity to experience pride in self ('hubristic' pride).

Shame, guilt, embarrassment, and pride are members of a family of 'self-conscious emotions' that are evoked by self-reflection and self-evaluation. This self-evaluation may be implicit or explicit, consciously experienced or transpiring beyond our awareness. But either way, the self is the object of self-conscious emotions. For example, when good things happen, we may feel a range of positive emotions – joy, happiness, contentment. But we feel pride in our *own* positive characteristics or actions. Similarly, when bad things happen, many negative emotions may arise – sadness, disappointment, frustration, anger. But feelings of shame and guilt typically arise from the recognition of one's *own* negative characteristics or behaviors. Even when we feel pride or shame due to another person's behavior, that person is apt to be someone with whom we are closely affiliated or identified (e.g., a family member, close friend). We experience shame because that person is part of our self-definition.

In contrast to 'basic' emotions (e.g., anger, fear, joy) which are present very early in life, self-conscious emotions have been described as 'secondary,' 'derived,' or 'complex' emotions because they emerge later and hinge on several cognitive achievements – recognition of the self separate from others and a set of standards against which the self is evaluated. For example, Lewis et al. (1989) showed that the capacity to experience embarrassment coincides with the emergence of self-recognition. Very young children first show behavioral signs of embarrassment during the same developmental phase (15–24 months) in which they show a rudimentary sense of self. Moreover, within this range, children who display self-recognition (in a 'rouge' test) are the same children who display signs of embarrassment in an unrelated task.

Also in contrast to 'basic' emotions, self-conscious emotions do not bear a one-to-one correspondence to clearly defined, facial expressions. Recent research has identified postural indicators of pride (e.g., head held high, shoulders back, Tracy and Robins, 2008), and there are physical signals of shame and embarrassment (slumped, shoulders, downcast eyes/head), but physical signs of shame and embarrassment are difficult to differentiate. These often subtle cues are not as readily apprehended as 'emotions of the face' such as anger, sadness, joy, and disgust. And there exists no known visible marker of guilt, on the face or otherwise. Thus, most researchers interested in the self-conscious emotions rely on self-report methods.

Shame and Guilt

The terms 'shame' and 'guilt' are often used interchangeably in everyday conversation. When people do distinguish the two, they typically suggest that shame arises from public exposure and disapproval of a failure or transgression, whereas guilt is more 'private,' arising from one's own conscience. Empirical research, however, has failed to support this public/private distinction. For example, Tangney et al. (1996a) found that people's real-life shame and guilt experiences are each most likely to occur in the presence of others. More important, neither the presence of others nor others' awareness of the respondents' behavior distinguished between shame and guilt. Overall, there are surprisingly few differences in the types of events that elicit shame and guilt. Shame is somewhat more likely in response to violations of social norms, but most types of events (e.g., lying, cheating, stealing, failing to help another) result in guilt for some people and shame for others.

So what is the difference between shame and guilt? Empirical research supports Helen Block Lewis's (1971) notion that shame involves a negative evaluation of the global self, whereas guilt involves a negative evaluation of a specific behavior. This differential emphasis on self ('*I* did that horrible thing') versus behavior ('I *did* that horrible *thing*') leads to different affective experiences.

Shame is an acutely painful emotion typically accompanied by a sense of shrinking, 'being small,' and by a sense of

worthlessness and powerlessness. Shamed people also feel exposed. Although shame does not necessarily involve an actual observing audience, there is often the imagery of how one's defective self would appear to others. Not surprisingly, shame often leads to a desire to escape or hide – to sink into the floor and disappear.

In contrast, guilt is typically less painful and devastating because the primary concern is with a specific behavior, not the entire self. Guilt does not affect one's core identity. (One can do a bad thing, but still be a good person.) Instead, when people feel guilt, they experience a tension, remorse, and regret over the 'bad thing done' and a nagging preoccupation with the transgression. Rather than motivating avoidance, guilt typically motivates reparative action.

Implications of Shame and Guilt for Interpersonal Adjustment

Research has consistently shown that, on balance, guilt is the more adaptive emotion, benefiting relationships in a variety of ways (Baumeister et al., 1994; Tangney, 1995). Three sets of findings illustrate the adaptive, 'relationship-enhancing functions' of guilt, in contrast to the hidden costs of shame.

First, the action tendencies associated with guilt are more apt to appease victims, repair relationships, and result in a better behavior in the future. Guilt often motivates reparative action – confessing, apologizing, undoing the harm that was done. In contrast, shame leads to attempts to deny, hide, or escape. Thus, guilt orients people in a more constructive, proactive, future-oriented direction, whereas shame orients people toward separation, distance, and defense (de Hooge et al., 2007; Lewis, 1971; Lindsay-Hartz, 1984; Sheikh and Janoff-Bulman, 2010; Tangney et al., 1996a).

Second, a special link between guilt and empathy has been observed at the levels of both emotion states and dispositions (Joireman, 2004; Leith and Baumeister, 1998; Stuewig et al., 2010; Tangney et al., 2007). For example, studies of children, college students, and adults (Tangney, 1995) show that guilt-prone individuals are generally empathic individuals. In contrast, shame-proneness is associated with an impaired capacity for other-oriented empathy and a propensity for 'self-oriented' personal distress responses. Similar findings are evident when considering feelings of shame and guilt 'in the moment.' Individual differences aside, when people describe personal guilt experiences, they convey greater empathy for others, compared to descriptions of shame experiences. It appears that by focusing on a bad behavior (as opposed to a bad self), people experiencing guilt are relatively free of the egocentric, self-involved focus of shame. Instead, their focus on a specific behavior is likely to highlight the consequences for distressed others.

Third, there is a special link between shame and anger, again observed at both the dispositional and state levels. At all ages, shame-prone individuals are also prone to feelings of anger and hostility. Moreover, once angered, they tend to manage their anger in an aggressive, unconstructive fashion. In contrast, guilt is generally associated with constructive means of handling anger (Tangney et al., 1996b). What accounts for this link between shame and anger? When feeling shame, people initially direct hostility inward ('*I'm* such a bad person'). But this hostility may be redirected outward in a defensive attempt to protect the self by shifting the blame elsewhere ('Oh what a horrible person I am, and damn it, how could you make me feel that way!'). Empirically, this relationship between shame and externalization of blame is especially strong and consistent across people from all walks of life. Moreover, evidence suggests that shame leads to aggression via its influence on externalizing blame (Stuewig et al., 2010).

In sum, studies employing diverse samples, measures and methods converge. All things equal, it is better if your friend, partner, child, or boss feels guilt than shame. Shame motivates behaviors that interfere with interpersonal relationships. Guilt helps keep people constructively engaged in the relationship at hand.

Implications of Shame and Guilt for Psychological Adjustment

Although guilt appears to be the more 'moral' or adaptive emotion when considering social adjustment, is there a trade-off vis-à-vis individual psychological adjustment? Does the tendency to experience guilt or shame leave one vulnerable to psychological problems?

Researchers consistently report a relationship between proneness to shame and a whole host of psychological symptoms, including depression, anxiety, eating disorder symptoms, subclinical sociopathy, and low self-esteem (Harder et al., 1992; Tangney et al., 2007). This relationship is robust across measurement methods and diverse populations.

There is more controversy regarding the relationship of guilt to psychopathology. The traditional view is that guilt plays a significant role in psychological symptoms. Clinical theory and case studies, including those of Freud, make frequent reference to a maladaptive guilt characterized by chronic self-blame and obsessive rumination over one's transgressions. On the other hand, recent theory and research has emphasized the adaptive functions of guilt, particularly for interpersonal behavior. Tangney et al. (1992) argued that once one makes the critical distinction between shame and guilt, there is no compelling reason to expect guilt over specific behaviors to be associated with poor psychological adjustment.

The empirical research is similarly mixed. Studies employing adjective checklist-type (and other globally worded) measures find both shame-proneness and guilt-proneness correlated with psychological symptoms. On the other hand, measures sensitive to the self versus behavior distinction show no relationship between proneness to 'shame-free' guilt and psychopathology (Tangney et al., 2007).

Implications of Shame and Guilt for Deterring Transgression and Socially Undesirably Behavior

Shame may be very painful, and it may carry with it considerable psychological baggage, but does it at least motivate people to avoid 'doing wrong,' decreasing the likelihood of transgression and impropriety? There is little direct evidence for this presumed adaptive function of shame when considering actual criminal behavior. To the contrary, research suggests that shame has little effect or may even make things worse. For example, in a study of college undergraduates, Tibbetts (2003) found that criminal offending was negatively related to guilt-proneness, but results for shame-proneness were mixed.

In a community sample of adolescents (Stuewig and McCloskey, 2005), proneness to 'shame-free' guilt negatively predicted delinquency; proneness to 'guilt-free' shame did not. In a large German sample of incarcerated adolescents and young adults (Hosser et al., 2008), single item shame ratings at the outset of incarceration predicted higher recidivism rates, whereas guilt ratings predicted lower recidivism. In large sample of adult jail inmates (Tangney et al., 2011), proneness to guilt was negatively correlated with criminal history, risk assessment measures, and psychological factors known to predict violent and nonviolent criminal recidivism. In contrast, inmates' shame-proneness was unrelated to clinician ratings of psychopathy and violent risk, and positively correlated with self-reported substance use, antisocial personality and criminogenic cognitions. In short, in the domain of crime, the experience of guilt clearly serves important inhibitory functions in ways that shame does not.

When Does Guilt Become Maladaptive?

Guilt is frequently cited as a symptom in such psychological disorders as depression, anxiety, and post-traumatic stress disorder (PTSD). What is the chronic problematic guilt described by so many clinicians? One possibility is that maladaptive guilt experiences are actually feelings of guilt *fused with shame*. When a person initially experiences guilt ('Oh, look at what a horrible *thing* I have *done*') but then magnifies and generalizes the event to himself or herself ('…and aren't I a horrible *person*'), many of the advantages of guilt are lost. In addition to feeling tension and remorse over a specific behavior, he or she is impaired by feelings of contempt and disgust for a bad self. For these reasons, shame-fused guilt may be just as problematic as shame itself.

Problems may also arise when people hold an exaggerated or distorted sense of responsibility for events beyond their control, as in survivor guilt associated with PTSD and other psychological problems (O'Connor et al., 2002; Kubany et al., 1995). Importantly, widely used scenario-based measures such as the Test of Self-Conscious Affect do not capture the propensity to experience guilt over events beyond one's control. In a meta-analysis of studies of shame, guilt, and depression (Kim et al., 2011), measures assessing 'legitimate' guilt (for events for which individuals have responsibility) showed little relationship to depression, whereas measures assessing guilt involving unrealistic responsibility for negative events were positively linked to depression.

Finally, there is some evidence that guilt can motivate self-denial or self-punishment when opportunities for reparation are blocked (Nelissen and Zeelenberg, 2009).

When Is Shame Adaptive?

The picture for shame is not entirely bleak. Some recent research in social psychology suggests that in some domains (e.g., academic) and under some conditions yet to be systemically examined, the experience of shame may motivate efforts to repair or improve oneself (de Hooge et al., 2008, 2010; Thompson and Berenbaum, 2006). In contrast, the conditions under which guilt motivates reparative or prosocial behavior are much broader in circumstance and personal attributes (de Hooge et al., 2007).

Embarrassment

Miller (1996) defines embarrassment as "an aversive state of mortification, abashment, and chagrin that follows public social predicaments" (p. 322). Indeed, embarrassment appears to be the most 'social' of the self-conscious emotions, occurring almost without exception in the company of others.

Causes of Embarrassment

In Miller's (1996) catalog of embarrassing events described by several hundred adolescents and adults, 'normative public deficiencies' (tripping in front of a large class, forgetting someone's name, unintended bodily induced noises) were at the top of the list. But there were many other types of embarrassment situations – awkward social interactions, conspicuousness in the absence of any deficiency, 'team transgressions' (embarrassed by a member of one's group), and 'empathic' embarrassment.

The diversity of situations that lead to embarrassment has posed a challenge to efforts at constructing a comprehensive 'account' of embarrassment. Some theorists believe that the crux of embarrassment is negative evaluation by others (Edelmann, 1981; Miller, 1996). This social evaluation account runs into difficulty with embarrassment events that involve no apparent deficiency (e.g., being the center of attention during a 'Happy Birthday' chorus). Other theorists subscribe to the 'dramaturgic' account, positing that embarrassment occurs when implicit social roles and scripts are disrupted. A flubbed performance, an unanticipated belch, and being the focus of 'Happy Birthday' each represent a deviation from accustomed social scripts.

Lewis (1992) distinguished between two types of embarrassment – embarrassment due to exposure and embarrassment due to negative self-evaluation. According to Lewis (1992), embarrassment due to exposure emerges early in life, once children develop a rudimentary sense of self. When children develop standards, rules, and goals (SRGs), a second type of embarrassment emerges – 'embarrassment as mild shame' associated with failure in relation to SRGs.

Functions of Embarrassment

Although there is debate about the fundamental causes of embarrassment, there is general agreement about its adaptive significance. Gilbert (1997) suggests that embarrassment serves an important social function by signaling appeasement to others. When untoward behavior threatens a person's standing in an important social group, visible signs of embarrassment function as a nonverbal acknowledgment of shared social standards, thus diffusing negative evaluations and the likelihood of retaliation. Evidence from studies of both humans and nonhuman primates supports this remedial function of embarrassment (Keltner and Buswell, 1997).

Embarrassment and Shame

Is there a difference between shame and embarrassment? Some theorists essentially equate the two emotions. A more dominant view is that shame and embarrassment differ in intensity

of affect and/or severity of transgression. Still others propose that shame is tied to perceived deficiencies of one's core self, whereas embarrassment results from deficiencies in one's presented self.

Research suggests that shame and embarrassment are indeed quite different emotions – more distinct, even, than shame and guilt. For example, comparing adults' personal shame, guilt, and embarrassment experiences, Tangney et al. (1996b) found that shame was a more intense, painful emotion that involved a greater sense of moral transgression. But controlling for intensity and morality, shame and embarrassment still differed markedly along many affective, cognitive, and motivational dimensions. When shamed, people felt greater responsibility, regret, and self-directed anger. Embarrassment was marked by more humor, blushing, and a greater sense of exposure.

Individual Differences in Embarrassability

As with shame and guilt, people vary in their propensity to experience embarrassment. These individual differences are evident within the first years of life, and are relatively stable across time. Research has shown that embarrassability is associated with neuroticism, high levels of negative affect, self-consciousness, and a fear of negative evaluation from others. Miller (1996) has shown that this fear of negative evaluation is not due to poor social skills, but rather a heightened concern for social rules and standards.

Pride

Of the self-conscious emotions, pride received the least attention, until recently. Most early research on pride comes from developmental psychology, particularly in the achievement domain. For example, Stipek and Recchia (1992) observed developmental changes in the criteria children use for evaluating success and failure, in the types of situation that lead to pride, and in the importance of praise from others.

Mascolo and Fischer (1995) defined pride as an emotion "generated by appraisals that one is responsible for a socially valued outcome or for being a socially valued person" (p. 66). They theorized that pride serves to enhance people's self-worth and to encourage future behavior that is socially valued.

Two Types of Pride?

Both Tangney (1990) and Lewis (1992) suggested that there are two types of pride. Paralleling the self versus behavior distinction of guilt and shame, Tangney (1990) distinguished between pride in self ('alpha' pride) and pride in behavior ('beta' pride). Similarly, Lewis (1992) distinguished between pride (arising from attributing one's success to a specific action) and hubris (pridefulness arising from attributions of success to the global self). Lewis (1992) viewed hubris as largely maladaptive, noting that hubristic individuals are inclined to distort and invent situations to enhance the self, which can lead to interpersonal problems.

Research over the past decade at multiple levels adopting multiple methods (Tracy and Robins, 2007) strongly supports this distinction between 'authentic' (or behavioral) pride and hubristic pride. And like shame and guilt, hubristic and authentic pride do not seem to be equally moral or adaptive emotions. At both the trait and state level, authentic pride is associated with a likable and socially desirable characteristics and prosocial behaviors, whereas hubris is associated with a more negative characteristics and antisocial behaviors (Tracy and Robins, 2007). For example, at the trait level, the two types of pride show divergent relations with achievement, mental health, social behavior, and relationship functioning (Carver et al., 2010; Tracy et al., 2009). People prone to authentic pride tend to be low in depression, trait anxiety, social phobia, aggression, hostility, and rejection sensitivity; and high in self-control, goal-engagement, relationship satisfaction, attachment security, dyadic adjustment, and social support. In contrast, people prone to hubristic pride are more impulsive, anxious, hostile, and inclined to engage in a range of other antisocial misbehaviors (e.g., drug use, petty crimes), and they report poorer relationship adjustment and social support.

Cultural Differences in Shame, Guilt, and Pride

Shame, guilt, and pride are emotions experienced in reference to self. To the extent that the nature of the self differs across cultures and nations (Markus and Kitayama, 1991), one might expect parallel differences in the experience and implications of self-conscious emotions. The research described thus far has been largely conducted in a Western context.

Most studies cross-cultural studies of the self-conscious emotions have compared Asian-Americans and Caucasian-Americans. Research consistently shows that Asian-Americans report more shame than their non-Asian-American counterparts, whereas cultural differences in guilt have been mixed (Lutwak et al., 1998; Tracy and Matsumoto, 2008). Regarding pride, there are clear cultural differences in the value attached to the emotion. Pride is a highly valued and sought out emotion in individualistic cultures (i.e., the United States, Australia, the Netherlands), whereas it is viewed as negative and undesirable in several collectivistic cultures (i.e., China, Spain, Taiwan; Eid and Diener, 2001; Mosquera et al., 2000).

Few studies have moved beyond a consideration of mean differences in proneness to shame, guilt, and pride, to consider the possibility of cultural differences in the *implications* of self-conscious emotions. Shame-proneness appears to be similarly associated with anger, depression, and anxiety among Asian-Americans and non-Asian-Americans, whereas the correlates of guilt are mixed. Two studies have examined cross-cultural continuities and discontinuities in the correlates of shame and guilt, comparing American-born children with Asian-born children living in their country of origin. Bear et al. (2009) reported a positive link between shame and anger among American children, but no such relationship among Japanese children. Comparing children residing in Japan, Korea, and the United States, Furukawa et al. (2012) found substantial group differences the propensity to experience self-conscious emotions. Japanese children scored highest on shame-proneness, Korean children scored highest on guilt-proneness, and the US children were highest on pride. Although it was hypothesized that shame would be less problematic among Japanese children relative to

those raised in Korea and the United States, because shame is more normative and would therefore be less painful in the self-critical Japanese culture, there were surprisingly few differences in the relationship of shame to aggression-related cognitions, emotions, and behavior.

New Directions in Research on the Self-Conscious Emotions

Much research has emerged on self-conscious emotions over the past two decades, but much work remains. Several promising new directions stand out, ensuring that the next two decades of research will be even more exciting than the developments described thus far.

First, researchers have become interested in the phenomena of 'vicarious' and group-based self-conscious emotions. Shame, guilt, embarrassment, and pride are typically experienced in reference to one's own attributes or behaviors. But people can also vicariously experience of self-conscious emotions owing to the actions of *other* individuals or groups. Some of the earliest research in this area focused 'empathic' or vicarious embarrassment (see Miller, 1996). More recently, investigators have examined 'vicarious' or 'group-based' shame and guilt (Lickel et al., 2007; Welten et al., 2012) which in many ways parallels findings regarding personal shame and guilt experiences. For example, as with personal guilt experiences, group-based guilt has been associated with empathy (Zebel et al., 2004) and a motivation to repair or make amends (Lickel et al., 2005). And as with personal shame experiences, vicarious group-based shame (but not guilt) has been linked to a desire to distance oneself from the shame-eliciting event (Lickel et al., 2005; Johns et al., 2005). Nonetheless, there are some indications that vicarious or group-based shame may have a 'kinder, gentler' side than personal shame. For example, under some circumstances, group-based shame appears to motivate a desire to change the image of the group in a proactive fashion (Lickel et al., 2006).

Second, much more research is needed on the phenomenon of 'guilt-tripping' and other efforts to use self-conscious emotions as a form of social control. Sharkey (1991) made important inroads in our understanding of 'intentional embarrassment.' To date, only a handful of studies have explicitly examined guilt induction (Baumeister et al., 1995; Vangelisti et al., 1991). These studies indicate that deliberate attempts to induce guilt occur relatively frequently, especially in the context of close relationships, and especially in response to real or perceived neglect. But many other questions remain. For example, what are the relative costs and benefits inducing shame, guilt, and embarrassment? How do those costs and benefits vary as a function of transgression, type of relationship, and personality characteristics of the inducee? Are some people more vulnerable than others to guilt (or shame or embarrassment) inductions?

Third, researchers have begun to explore context- or domain-specific shame and guilt. For example, researchers concerned with the psychology of eating disorders have assessed feelings of shame specifically in reference to one's body. 'Body shame' has been consistently associated with self-objectification and eating disorder symptoms (e.g., Tiggemann and Boundy, 2008). Other researchers have examined the nature and implications of trauma-related guilt cognitions, such as false beliefs about responsibility or preoutcome knowledge, which are reliably associated with symptoms of depression among trauma survivors (Kubany et al., 1995).

Fourth, exciting discoveries are being made about the psychobiological correlates of the self-conscious emotions. For example, increases in shame (but not guilt or general negative affect) coincide with increased proinflammatory cytokine activity (Dickerson et al., 2004). Experiences of shame have also been linked to elevated cortisol (Gruenewald et al., 2004) as well as distinct patterns of cardiovascular reactivity (Herrald and Tomaka, 2002). Regarding brain regions associated with self-conscious emotions, activation of medial prefrontal cortex and the posterior superior temporal sulcus have both been implicated in the experience of embarrassment and guilt, based on functional magnetic resonance imaging research (for a review, see Robins and Schriber, 2009).

Conclusions

Understanding the self-conscious emotions is critical to understanding the self. Psychological researchers have made much progress since the first comprehensive volume addressing the science of shame, guilt, embarrassment, and pride (Tangney and Fischer, 1995) but there remain many unanswered questions ripe for inquiry. Perhaps more than other emotions, the measurement of self-conscious emotions poses some real challenges. A number of measurement methods have been developed in recent years (see Robins et al., 2007; for a review), but the coming decades will no doubt see improvements in our ability to assess these emotions, enhancing this burgeoning area of research.

Self-Control Theory and Crime

Abstract

This article provides an overview of Gottfredson and Hirschi's (1990) self-control theory. The article details the development. The development pertains to the role of parents and schools. Gottfredson and Hirschi argue that peer association is not an issue with their theory. This article discusses the issues surrounding this viewpoint. In addition, it discusses gender differences. Each of these topics is applied to criminal and deviant behavior.

Attempts to discern the causes of crime have occupied criminologists for many years. These attempts generally manifest themselves in new theories of crime, or more commonly in support of those that are already established. These theories have a variety of foci, ranging from characteristics unique to the individual to those that relate to the environment in which they reside. Although some theories are targeted at specific environments or forms of offending, recent developments can be considered to be more general in nature. That is, they purport to explain a range of crime, occurring in a variety of settings. One such theory, Gottfredson and Hirschi's General Theory of Crime (1990), suggests that this behavior occurs as a result of low self-control, and that levels of self-control are influenced early in life through the socialization process. This article will relay the core tenets of the theory, including the relationship between self-control and crime and the influence that parents and other institutions have on the development of self-control. It will then proceed to provide a brief overview of the supporting literature, and conclude with a discussion of potential policy implications arising from its propositions.

Gottfredson and Hirschi's General Theory of Crime

Whereas most criminological theories seek to detail the factors that contribute to crime, self-control theory seeks to understand what keeps the majority of society from participating in it. Gottfredson and Hirschi (1990) view such behavior as resulting from an inability to refrain from acting when opportunities to offend arise, simply due to the fact that these opportunities present the possibility of pleasure for the offender. In this sense, they view all individuals (even those who commit criminal acts) as being able to rationally calculate the potential pleasure and pain associated with an act, and in the event that the pleasure outweighs the costs, able to act upon their desires. Costs can take many forms, and include potential criminal sanctions, loss of job or status, and/or harm to personal relationships. Most individuals are able to comprehend the magnitude of these costs and refrain from committing the deviant act. However, some individuals seem to lack this ability. Gottfredson and Hirschi contend that this occurs due to a lack of self-control. In other words, some individuals are impulsive and shortsighted. These characteristics lead their rational processes to be bounded in a sense, meaning that the only factors that they weigh are those immediate to the situation. Since immediate benefits are much easier to comprehend than long-term costs, deviant acts become all the more likely for these individuals.

The Development of Self-Control

Gottfredson and Hirschi suggest that self-control is developed early in life, primarily through the socialization process. This process depends on a number of parties, ranging from parents (posited to be most important) to social institutions. Since parents are most responsible for the development of the child, their role is especially important in the socialization process. According to their conceptualization, four specific parental factors contribute to the development of self-control: attachment, behavior monitoring, behavioral evaluation, and corrective actions. Attachment is especially important due to the fact that without it, none of the other actions are likely to be taken. In essence, parents who bond with their children are more likely to take an interest in their development and behavior. This interest allows them to fulfill the second requirement, that behavior is monitored on a regular basis. Due to their young age and inexperience with societal norms, children lack an innate understanding of how to act in a proper manner. Parents are charged with observing their actions, and gaining an understanding of their overall behavior. This information-gathering process allows them to fulfill the third component, behavioral evaluation, and to take note of that which they do not deem proper. Once this behavior is noticed, corrective action can be taken in an attempt to show children their wrongdoings and prevent reoccurrences in the future. This process of observation and correction, if consistent, ultimately allows children to gain their own understanding of what is expected by society.

It is important to note that this four-part process must occur early in the child's development. According to Gottfredson and Hirschi, self-control is established in most instances by the age of 8 and few changes can occur after this stage. Thus, children with low self-control due to poor parenting practices are unlikely to alter their level at a later date even if parenting is improved. Children, due to impulsivity and shortsightedness, will be inclined to make bounded decisions, and thus be at greater risk for antisocial or criminal behavior than their peers who have parents who took an interest in their socialization.

While parents have the unique ability to shape a child's behavior due to the sheer amount of time that they spend with

them, they are not alone in the socialization process. Schools and other social entities (e.g., churches) are in a unique position to frame behavior as well. Once children enter into the educational system – whether it be in preschool or in kindergarten – they spend a significant portion of their time interacting with teachers and other school staff. This time involves those individuals taking a unique interest in the child. This interest manifests itself not only in providing quality education but also in ensuring proper behavior. Since effective classrooms depend on cooperation from students, teachers are charged with observing and regulating behavior. Improper behavior – or that antisocial in nature – is quickly addressed through means of punishment available within the school. Furthermore, information can be transmitted to the misbehaving child's parents in order for them to take external action. Ideally, this 'team effort' of behavioral observation and correction should allow the socialization process to take hold much more easily than if just the parents were responsible for it.

Unfortunately, not all school settings are conducive to behavior regulation. Schools featuring poor management and high levels of disorder are unlikely to assist in the process. On the other hand, even those schools and teachers who take appropriate interest in the child are not necessarily guaranteed to have parental cooperation. Parents who have not bonded appropriately with the child – and who have little interest in their away-from-home behavior – are unlikely to take corrective actions. Thus, while the socialization process is undertaken by teachers and other staff, it is unlikely to result in the development of high self-control since the parents are not reinforcing the norms at home.

A General Theory of Crime

As mentioned within the introduction, Gottfredson and Hirschi's theory is considered a general theory of crime. In other words, they posit that it is applicable to all forms of offending, as well as to all individuals and groups. Furthermore, they believe low self-control to be the primary cause of offending, with other factors culminating in it (e.g., poor parenting practices). This is unique to the extent that a review of the most popular theories of crime reveals a plethora of potential factors influencing the decision to commit deviant acts. Thus, the potential for one theory to have applicability to all criminal decision making offers a great deal of promise to the field.

In addition to this potential benefit, the theory is designed in a manner to allow testing in any number of settings and with nearly any form of data. Many theories require longitudinal data in order to show some manner of causality, whereas self-control theory can be tested using cross-sectional data. Since self-control is deemed to be stable throughout the life course (following the age of 8), queries regarding the individual's impulsivity, short-sightedness, and preference for easy, immediate gratification allow researchers to gather the information necessary to tie their level of self-control to any criminal acts that they may have committed. The development of a scale of self-control by Grasmick et al. (1993) has greatly assisted in this regard, and continues to be used within the field today.

Peer Groups and Low Self-Control

Having now briefly discussed the development of low self-control and Gottfredson and Hirschi's conceptualization of a general theory of crime, attention is turned to discussing its ramifications. As mentioned, low self-control manifests itself in deviant acts due to a shortsightedness on the part of the afflicted individual. These acts begin relatively early in life, though they may be relatively minor at first (e.g., acting out within the school setting). It is the introduction to deviant peer groups that is likely to set in motion the path to more serious acts. While some theories view these groups as the primary cause of offending – as they introduce individuals to the proper techniques required for it – Gottfredson and Hirschi suggest that it is low self-control that leads individuals to join such groups in the first place. In other words, those with low self-control are drawn to similar individuals due to the fact that they view them as fun and willing to take chances much as they are.

Combining these individuals into one peer group may lead to a reinforcement of sorts, and make the commission of crime easier. The suggestion of other theoretical premises that ideas are learned within these groups is not dismissed by self-control theory. Nor is the fact that strength in numbers may exacerbate offending. In fact, both these factors are viewed as being in play. However, it is stressed that this alone is not enough for individuals to embark upon a life of criminality. Their low level of self-control makes them more likely to associate with this type of group, just as it makes them more likely to commit deviant acts. The combination of both these likelihoods only serves to increase the potential for crime.

The Role of Gender in Self-Control Theory

As criminological theory has developed, attention has been directed at the role that gender plays in offending. That is, it is suggested by many that differences do exist between males and females. Gottfredson and Hirschi have received some criticism for their perceived slight to this notion due to the fact that they argue that the same socialization processes are at play in the criminality of both girls and boys. However, the theory does address potential gender issues by suggesting that girls are more likely to feature higher levels of self-control, and are thus less likely to participate in deviant behavior. Research indicates that girls are significantly less likely to offend throughout the lifecourse, reinforcing this proposition. The question must thus be asked, why do girls feature these higher levels? Gottfredson and Hirschi suggest that parents take a greater interest in the behavior of these girls than they do in their male counterparts. This is due to the fact that they are more concerned with potential misbehavior by them and the consequences that such misbehavior might bring. Attachment is thus much higher, and the socialization process is facilitated by it. Having now discussed the core components of self-control theory, attention is now turned to support for theory, with specific focus on recent research within the field.

Support for Self-Control Theory

Over three decades have passed since Gottfredson and Hirschi put froth their General Theory of Crime. During this time a rather large number of researchers have tested their core tenets, with a great deal of support emerging. Perhaps the most exhaustive overview of this research can be found in

a meta-analysis published by Pratt and Cullen (2000). The researchers found that while Social Learning Theory explained a portion of deviant behavior, low self-control constituted a significant predictor across a wide range of samples and behaviors. Furthermore, this predictive power existed regardless of the way in which self-control was measured, offering additional support for the theory. (An additional discussion of the influence of self-control regardless of measurement can be found in the work of Tittle et al. (2003).) In the time since this analysis was published, a plethora of new studies have emerged, offering both additional support and unique insights into the role that self-control plays in deviant acts. These studies can be grouped based on the core tenets of the theory: the role of parenting, development of low self-control, gender differences, and the influence of low self-control on peer group affiliation and deviant behavior. Empirical support for each of these tenets will now be briefly reviewed.

Support for the Role of Parenting

As discussed, parenting plays the key role in the socialization process, and thus in the development of higher levels of self-control. This notion has been tested time and again, and has shown itself to be rather well-supported (Hay, 2001; Gibbs et al., 1998; Gibbs et al., 2003). It appears as if those parents who bond with their children – and thus monitor and control their behavior – facilitate in the development of higher levels of self-control (Finkenauer et al., 2005). Trajectory analysis has further revealed that levels of self-control may increase linearly through the years of early development, and shares a significant relationship with parenting at each point in time (Vazsonyi and Huang, 2010). Thus, consistent application of the monitoring and corrective processes detailed earlier in this piece appears to be incredibly important in ensuring higher levels of self-control once the child reaches the age of 8.

Some research has been directed at determining if any additional factors beyond parenting and other social institutions play a part in the development of low self-control. This research has specifically focused upon community context, and the role that certain neighborhood factors (e.g., poor economic conditions) play upon the development of the individual. For example, Wikstrom and Sampson (2002) argue that the collective efficacy of a community plays a role in behavioral identification and thus correction. This suggestion has received some support (Pratt et al., 2004). However, when controlling for individual characteristics it appears that the role of community context may be a nonsignificant predictor – further supporting the role of parents (Gibson et al., 2010).

Of unique interest is recent evidence suggesting that levels of self-control may be transmitted from parents to child (Boutwell and Beaver, 2010). This transmission is posited by some to be genetic in nature, thus making low levels of self-control less reliant upon socialization than upon biological predisposition (Beaver et al., 2010; Wright et al., 2008). With that said, this postulation is to date understudied, and the potential exists that both socialization and biological factors may work together in the development of self-control (Boutwell et al., 2013).

Support for the Stability of Self-Control

Recall that self-control was posited by Gottfredson and Hirschi (1990) to be fully developed by the age of 8 and remain relatively stable throughout the lifecourse. This proposition has been met with mixed results. Supporting their conceptualization, it has been found that a significant proportion of people remain relatively stable in their level of self-control after the age of 8 (Higgins et al., 2009). However, this does not apply to all, as others have found that a smaller group has the potential for variation well into adolescence (Hay and Forrest, 2006; Hay et al., 2010). This variation can feature improvement to higher levels of self-control, or regression to lower levels. Variation can occur for a variety of reasons, including victimization. For example, it has been found that individuals who experience victimization have the potential for their levels of self-control to be reduced in the near term due to the strain that it imposes (Agnew et al., 2011). Peer association may play a role as well, as information learned within peer groups may lead to changes in control over time, especially for those experiencing relatively low levels of self-control to begin with (Jennings et al., 2013). Ultimately, it may be useful to view self-control as relatively stable, with the potential for certain factors to produce variation over time.

Support for Gender Differences

Gottfredson and Hirschi (1990) suggest that gender differences exist within their theory to the extent that girls are more likely to be properly socialized through parental monitoring than are boys. Research on the link between self-control and deviant behavior in general suggests that boys are more likely to feature low self-control than girls, partially supporting this hypothesis (Shekarkhar and Gibson, 2011). However, recent investigations into impulsivity reveal that while girls are more likely to feature these higher levels, better parental monitoring may not be the cause. For example, Chapple and Johnson (2007) suggest that boys simply experience differential effects in relation to less constrained familial environments. In other words, when monitoring and control are not present, boys are more likely to develop lower levels of control than their female counterparts. With that said, an understanding of gender differences on the development of self-control remains somewhat fleeting. The suggestion has been raised that the way in which girl's self-control is measured and modeled needs improvement (Chapple et al., 2010; Higgins, 2004). Thus, until a better understanding of all the variables that influence self-control is achieved, gender differences are likely to remain a mystery of sorts.

Support for Peer Groups and Deviant Behavior

Gottfredson and Hirschi's (1990) conceptualization of self-control and its influence on behavior has been applied to a range of deviant acts, and is generally met with great support. Recall the proposition that peer groups are not the origin of deviant behavior, but that those with low self-control are drawn to groups composed of similar individuals. Research suggests that this phenomenon does in fact exist (Wolfe and Higgins, 2009; McGloin and Shermer, 2009). Furthermore, it may occur

as a result of their rejection – due to their predisposition – by more traditional peer groups (Chapple, 2005). In other words, the inability of these individuals to associate with nondeviant peers leads them to take refuge in groups of others with low self-control. Once in these groups, the opportunity for offending is only magnified as new avenues are presented to them.

While a complete examination of all forms of antisocial actions explained by low self-control is beyond the scope of this article, it is important to note that it can be applied to nearly any type of behavior. Pratt and Cullen's (2000) meta-analysis of research published throughout the 1990s revealed strong initial support for this notion, as the studies included varied in the behavior that they focused upon. In the time period since, it has been applied to everything from violent offending to imprudent behavior (i.e., academic fraud, binge drinking) (Piquero et al., 2005; Reisig and Pratt, 2011). Furthermore, it has application in relation to relatively modern forms of offending such as software piracy (Higgins et al., 2008). Perhaps most supportive of the relationship between low self-control and deviant behavior is the work of Vazsonyi et al. (2001). Empirical analysis of data from four countries revealed that low self-control played a similar role in the decision to offend across all individuals. Furthermore, it predicted deviant behavior in relation to a range of offenses, from vandalism to drug use. Taken as a whole, it appears that the relationship between self-control and antisocial propensities is rather strong in nature.

Conclusion

In summation, support for the role of self-control in offending seems rather robust, as the good majority of Gottfredson and Hirschi's propositions are backed by the literature. Parenting and schools do seem to play key roles in the development of self-control, with poor monitoring resulting in lower levels of it. Though some variation exists in levels of self-control throughout adolescence, it appears that for the majority of individuals it is relatively stable past the age of 8. Furthermore, low self-control can be tied to a range of deviant acts, and is in most instances shown to be one of the primary causes of such behavior. With that said, much work is still to be done. Gender differences in the development of self-control remain poorly understood, and recent suggestions that biological factors may be at play in the transmission of it from parent to child are deserving of further consideration.

In addition, Hirschi (2004) has since attempted to reconceptualize his stance on control, suggesting that bonds and human agency (rational calculation) play a greater role than previously suggested. Furthermore, he contends that self-control is not so much a personality trait of the individual that remains constant over time, but rather something to be considered in the decision-making process. This development is likely to lead to a reanalysis of the other facets of the theory, and include new questions presented in relation to gender, stability, and the role of parenting and social institutions. At the least it should present researchers with new opportunities for investigation, offering the potential for our understanding of the relationship between control and offending to be further developed in the coming years.

Abstract

Self-determination Theory (SDT) is a motivational theory of personality, development, and social processes that examines how social contexts and individual differences facilitate different types of motivation, especially autonomous motivation and controlled motivation, and in turn predict learning, performance, experience, and psychological health. SDT proposes that all human beings have three basic psychological needs – the needs for competence, autonomy, and relatedness – the satisfaction of which are essential nutrients for effective functioning and wellness. Satisfaction of these basic needs promotes the optimal motivational traits and states of autonomous motivation and intrinsic aspirations, which facilitate psychological health and effective engagement with the world.

Self-determination Theory (SDT) is a theory of human motivation that examines a wide range of phenomena across gender, culture, age, and socioeconomic status. As a motivational theory, it addresses what energizes people's behavior and moves them into action, as well as how their behavior is regulated in the various domains of their lives. SDT's explanations are focused at the psychological level (rather than the sociological or physiological levels), thus using human perceptions, cognitions, emotions, and needs as predictors of regulatory, behavioral, developmental, and experiential outcomes (e.g., Ryan and Deci, 2000b).

Central to the theory is the important distinction between two types of motivation – *autonomous motivation* and *controlled motivation*. Traditionally, motivation theories have treated motivation as a unitary concept focusing just on the total amount of motivation people have for behaviors in order to predict how vigorously they will engage in those behaviors, and many contemporary theories of motivation still do. SDT, in contrast, has always put its primary emphasis on the types of motivation people have for various behaviors. The theory maintains that, although knowing the amount of motivation people have for behaviors may allow one to predict the amount or quantity of the behaviors they will exhibit, assessing types of motivation is necessary for predicting the quality and maintenance of those behaviors.

When people are autonomously motivated, they act with a full sense of willingness and volition, wholly endorsing that which they are doing because they find it either interesting and enjoyable, or consistent with their deeply held, integrated values. Autonomous motivation is typically accompanied by the experience of positive affect, flexibility, and choice. In contrast, when people's motivation is controlled, they act out of coercion, seduction, or obligation. They tend to experience pressure and compulsion, rather than concurrence and choice. Much of the self-determination research has examined either (1) antecedents of these types of motivation, at the developmental or the situation levels, or (2) the concomitants and consequences of the different types of motivation. We address these two types of motivation and their various subtypes in turn, although first we speak briefly about the philosophical assumptions upon which self-determination was built.

The Meta-Theory of SDT

Within psychology, the meta-theoretical assumptions underlying different theories tend to fall along a continuum from mechanistic to organismic. At one end, mechanistic meta-theories assume that humans are passive and thus require some force operating on them to move them into action. Classic theories of this sort include operant theory (Skinner, 1971), which assumes that external reinforcers, such as contingently provided food and water, as well as their derivatives such as money, are what move people into action. When reinforcers are provided after a person emits a behavior in the presence of a contingency, the reinforcer will strengthen the association between the contingency and behavior, making the behavior more likely to occur the next time the contingency is present.

At the other end of the continuum, organismic meta-theories assume that humans are by nature active organisms who can motivate themselves to act on their environment and elaborate and strengthen their understanding and behavioral repertoire. Piaget's (1971) theory of cognitive development is an example of a classic theory built upon organismic assumptions. This approach assumes that people are naturally inclined to expand their cognitive, knowledge structures by seeking stimuli that are optimally discrepant from their existing structures. The assimilation schema is the means through which these new schema are developed, and the organization principal is the process that integrates the new schema into people's existing structures.

Many current theories, such as the social cognitive and social learning theories (e.g., Bandura, 1996) fall somewhere between the ends of the continuum with some aspects of the theories reflecting somewhat mechanistic, and others reflecting somewhat organismic, meta-theoretical assumptions. However, the primary lacuna in these theories is the failure to recognize that people have an innate developmental tendency – that is, that they inherently act to elaborate themselves and to integrate these new experiences. Simply stated, from the organismic perspective, development is not something the environment does to people, although of course the environment does affect people's development; rather development is something that people do for themselves by acting on stimuli either that they seek out or that are thrust upon them.

Self-determination theory (SDT) is decidedly organismic at its core. It assumes that humans are active, working to integrate new material into their own sense of self, but also, and importantly, that the environment can either provide nutrients for this integrative process, or can disrupt and impair the process. Thus, it is the dialectic between the active, growth-oriented organism and the social context that is the central explanatory nexus for motivation, behavior, and development. The degree to which people's motivation is autonomous versus controlled, at either the developmental or situation level, depends on the degree to which the active integrative process functions more versus less successfully, in part depending on whether the social environment supports versus thwarts the integration.

Autonomous Motivation

The early motivation research that led directly to SDT differentiated intrinsic motivation from extrinsic motivation (e.g., Deci, 1971). Intrinsic motivation means people are engaging in an activity because they find it interesting, enjoyable, or fun. The play of young children is a perfect example of intrinsically motivated behavior. The children are active and engaged in a very natural way. They will often be working out some inner agenda, such as expressing feelings, albeit without any deliberate intention to do so. They are simply doing what they find interesting to do, and in the process they are learning and growing. Adults are also intrinsically motivated for some activities, typically their leisure-time pursuits. Because intrinsic motivation is a natural internal motivation involving interest and enjoyment, it is not necessary to motivate people to do what they find intrinsically interesting. They simply do those behaviors and this intrinsic motivation is the prototype of autonomous motivation.

Intrinsic motivation is often discussed in contrast to extrinsic motivation. The latter type of motivation involves a contingency between the target behavior and some separable consequence desired by the individual. What are referred to as reinforcers in operant theory can be thought of as extrinsic motivators. People are often extrinsically motivated by the pursuit of rewards such as money or prizes, the avoidance of noxious stimuli, or the desire for social approval. Colloquially, the classic extrinsic motivators are the 'carrot and stick.'

Intrinsic and Extrinsic Motivation

Early intrinsic motivation research examined the effects of extrinsic rewards on intrinsic motivation. At issue is whether giving extrinsic rewards to people who are intrinsically motivated for an activity would enhance their intrinsic motivation for the activity. That of course would be desirable. Perhaps, however, the two are additive in which case the motivations would not affect each other but would add together to form total motivation. That too would be a good outcome. But the third option is that there is a negative interactive effect between extrinsic rewards and intrinsic motivation. That would mean that giving extrinsic rewards to someone doing an interesting activity would actually diminish the person's intrinsic motivation for the activity.

The initial research indicated that in fact extrinsic rewards do undermine intrinsic motivation (Deci, 1971). People who did an interesting activity to get a monetary reward were subsequently less intrinsically motivated than others who did the same activity without getting the reward. This was a very controversial finding because it highlighted negative effects of rewards, which is no doubt the archetype of motivation in most people's minds, and of course in the behavioral psychologies. So, in the subsequent decades there were many additional tests of this phenomenon. A meta-analysis of more than 100 experiments confirmed that tangible rewards do in fact undermine intrinsic motivation for a behavior, especially if the rewards are contingent on the behavior, expected while doing it, and relatively salient (Deci et al., 1999). On the other hand, the research and meta-analysis also showed that positive feedback enhanced intrinsic motivation. Additional experiments showed, as summarized by Ryan and Deci (2000a), that threats of punishment, deadlines, evaluations, and surveillance all undermined intrinsic motivation, whereas providing people with choice, as well as acknowledging their feelings and perspectives, tended to enhance their intrinsic motivation.

In drawing these findings together and providing a theoretical account, Deci and Ryan (1985) posited that integral to intrinsic motivation are two fundamental psychological needs – that is, the needs for autonomy and competence. Stated differently, people have inherent psychological needs, just as they have basic physiological needs (e.g., oxygen, food, and water), and satisfaction versus thwarting of the basic psychological needs can have a range of positive versus negative consequences. Specifically, people may become dependent on and controlled by external events such as tangible rewards, threats, deadlines, and surveillance, thus having their need for autonomy thwarted and their intrinsic motivation undermined by these events. In contrast, choice and the acknowledgment of their internal perspective have been found to increase people's sense of autonomy, thus enhancing their intrinsic motivation. Concerning feedback, positive feedback tends to affirm people's sense of effectance, thus satisfying their need for competence and enhancing their intrinsic motivation; whereas, negative feedback, which has been found to diminish intrinsic motivation, is thought to have its effects by thwarting the need for competence.

Internalization of Motivation

The fact that the most typical extrinsic motivators have been reliably found to decrease intrinsic motivation – humans' natural, inherent type of autonomous motivation – raises the question of whether it is possible for people to be autonomous while being extrinsically motivated. Ryan et al. (1985) addressed that issue with the concept of internalization, which had been an important concept in developmental psychology for many years, and they suggested that people tend to internalize material endorsed by significant others in order to satisfy a basic psychological need for relatedness. The Ryan et al. idea was that extrinsic contingencies, which are external to people, could be taken in by the individuals and integrated into their sense of self. If that were to happen, people could behave from their own sense of self and thus be autonomous with respect to motivations that had originally been external.

However, the researchers pointed out that internalization, which is a natural part of the integrative process, may not always function wholly effectively so motivations sometimes get only partially internalized and thus not fully integrated. Therefore, they suggested, internalization can be understood in terms of a continuum of autonomy, in which the more fully some value or regulation is internalized the more the accompanying behavior will be enacted autonomously. They discussed four types of extrinsic motivation that resulted from different degrees of internalization.

External regulation is the classic type of extrinsic motivation. People behave because of external contingencies that have not been internalized. Thus, external regulation is the least autonomous and most controlled form of extrinsic motivation. *Introjected regulation* results from people having partially internalized an extrinsic motivation – that is, having taken it in but not really accepted it as their own. Introjection includes being motivated by contingent self-esteem, guilt, or ego-involvement. Introjected regulation has been found empirically to be accompanied by experiences and consequences similar to those associated with external regulation. Thus, although this type of extrinsic motivation is internal to the person, it is still quite controlling. A more fully internalized form of extrinsic motivation is referred to as *identified regulation* because it involves people identifying with the personal value and importance of the behavior for themselves and thus accepting it as their own. Subsequently, they will regulate themselves for related behaviors relatively autonomously. Finally, the fullest type of internalized extrinsic motivation is labeled *integrated regulation*. It involves people having integrated new identifications with other aspects of their own integrated sense of self – that is, with other identifications, values, and needs. With integrated regulation, people act with a full sense of volition and choice. Empirically, identified regulation is more closely related to integrated regulation than it is to introjected regulation. Thus, identified and integrated regulations, as well as intrinsic motivation, are all considered relatively autonomous forms of motivation.

With the elaboration of extrinsic motivation in terms of the degree of internalization, and thus of autonomy, it became clear that the distinction between autonomous and controlled motivation was the most useful and appropriate as the primary distinction in SDT. Accordingly, autonomous motivation comprises external and introjected forms of extrinsic motivation, whereas controlled motivation comprises identified and integrated forms of extrinsic motivation, along with intrinsic motivation. In this, one sees that some types of extrinsic motivation (identified and integrated) are relatively autonomous along with intrinsic motivation and one type of internal motivation (introjected) is relatively controlled. As such, neither the intrinsic–extrinsic distinction, nor the internal–external distinction works as cleanly and effectively as the autonomous-controlled distinction.

Autonomy across Cultures

Various psychologists have argued that the concept of autonomy is a Western concept that is not relevant to Eastern cultures (e.g., Iyengar and DeVoe, 2003); however, numerous studies have shown that the experience of autonomy is also essential in various Eastern cultures such as South Korea, China, and Japan. For example, Chirkov et al. (2003) did a study in Korea, Russia, Turkey, and the United States, finding that when people enacted behaviors consistent with either individualism or collectivism and did so autonomously, they evidenced high well-being, but when their enactment was prompted by controlled motivation, they evidenced poor well-being, regardless of the culture or the values. In other words, autonomy is necessary for a high level of psychological wellness in Eastern as well as Western cultures.

Amotivation

Clearly, both autonomous and controlled motivations are types of motivation, so to whatever degree people have one or the other or both of these, the people will be motivated. In contrast, the concept of *amotivation* refers to people having no intentionality or motivation. People tend to be amotivated for a behavior when they do not feel competent to do it or when they do not value the outcomes that are likely to follow from the behaviors.

Many motivation theories use as their primary distinction: being motivated versus unmotivated. SDT, however, has a tripartite differentiation of autonomous motivation, controlled motivation, and amotivation. Considerable research has used questionnaires that assess these concepts at the levels of specific behaviors, such as stopping tobacco use, or of domains, such as doing schoolwork. However, the tripartite conceptualization has also been examined at the more general personality level.

Causality Orientations

The concept of general causality orientations refers to three individual difference variables related to people's understanding of the causality for their behaviors and the degrees to which, motivationally, they are generally oriented in these ways. The three causality orientation dimensions are the autonomous orientation, the controlled orientation, and the impersonal orientation (Deci and Ryan, 1985). When people are high in the autonomous orientation, they tend to focus on information in the environment and within themselves that they can use in making choices, and they tend to have a high level of autonomous motivation. When people are high in the controlled orientation, they tend to focus on controls and pressures in the environment and within themselves that tell them what they should do, and to a substantial degree their behavior is controlled. When people are high in the impersonal orientation, they tend to focus on cues in the environment and within themselves that signify their incompetence and inability to obtain desired outcomes, and they tend to be amotivated a good deal of the time.

Each person has each of these orientations to some degree, so people are not categorized as being one type of person or another. Rather, the three orientations are all operative to differing degrees, and each orientation influences some of their behaviors and experiences. The autonomous orientation is related to self-esteem and self-actualization; the controlled

orientation is related to public self-consciousness and the type-A coronary-prone behavior pattern; and the impersonal orientation is related to self-derogation and depressive symptoms.

Basic Psychological Needs

Earlier we introduced the concept of fundamental psychological needs, which refers to essential, universal nutrients for psychological health and well-being. We mentioned that satisfying the needs for competence and autonomy appeared to be particularly important for maintaining intrinsic motivation, and also that people tend to internalize extrinsic motivation in order to experience satisfaction not only of these needs but also the need for relatedness.

Indeed, the concept of basic psychological needs is central to SDT because it specifies the nutrients that are essential in the environment to support and facilitate people becoming more autonomously motivated, experiencing greater psychological and physiological wellness, and performing more effectively (Gagné and Deci, 2005; Ryan et al., 2008b). Many dozens of studies, summarized in a recent meta-analysis (Ng et al., 2012) have confirmed that, across cultures, genders, and circumstances, when people experience satisfaction of the three basic psychological needs, they do indeed evidence greater health and well-being.

The importance of supports for psychological need satisfaction has been shown concurrently and developmentally. First, some studies have shown that when the current social environment supports one or more of the basic needs, people tend to be more autonomously motivated in that situation. Examples of this are the experiments showing that both choice and acknowledging people's feelings in a particular situation enhanced their intrinsic motivation for the target activity at that time (Deci et al., 1999). When environments supported people's autonomy, they became more intrinsically motivated. Similarly, an experiment (Deci et al., 1994) showed that supports for autonomy in a particular situation facilitated internalization and integration in that situation.

Second, the promotion of autonomous motivation and wellness has been shown developmentally. For example, studies have shown that when the social contexts of either homes or classrooms were autonomy supportive of young students, the students tended, over time, to develop stronger identifications with the importance of doing schoolwork – that is, they internalized this value and regulation more fully (Grolnick and Ryan, 1989). As noted already, the concept of general causality orientations concerns people's general individual differences with regard to autonomous and controlled motivation and amotivation. This concept of causality orientations is viewed as a developmental outcome – that is, it is said to result from the mix of supporting versus thwarting of the basic psychological needs during one's developmental years. When all of the needs are satisfied over time, in homes, schools, and elsewhere, while children are growing up, they tend to develop a relatively strong autonomy orientation. When the competence and relatedness needs are supported, but the need for autonomy is thwarted, people tend to develop a fairly strong controlled orientation, and when all of the needs are relatively thwarted, people tend to develop a high level of the impersonal orientation. In short, the satisfaction versus thwarting of the basic psychological needs for autonomy, competence, and relatedness explains the enhancement versus undermining of intrinsic motivation, the internalization of extrinsic motivation, and the development of general causality orientations.

Hedonic and Eudaimonic Wellness

Basic psychological needs theory was developed initially to address the issue of psychological wellness, although it has a central role in all of SDT, for satisfaction of the psychological needs has been shown to maintain and enhance intrinsic motivation, to promote internalization of extrinsic motivation, and to facilitate development of the causality orientations. As well, it has consistently been shown to promote well-being. Within that field, a distinction is frequently made between hedonic well-being and eudaimonic well-being (Ryan et al., 2008a). Hedonic well-being refers to being happy, to having high positive affect and low negative affect. Eudaimonic well-being, in contrast, refers to living one's life in a full and deeply satisfying way, actualizing one's human potentials. Eudaimonic living will often be accompanied by positive affect, but people will also experience negative affect when that is appropriate to the moment, as when something sad has just happened. Satisfaction of the basic psychological needs has been shown to be crucial for eudaimonic well-being.

Need Support, Motivation, and Outcomes

Much of the research examining the consequences of autonomous motivation, controlled motivation, and amotivation has been done in various applied settings, including homes, schools, workplaces, medical clinics, athletic settings, psychotherapy offices, and virtual worlds. In short, many hundreds of studies have shown that, across these domains in many countries, outcomes tend to be most positive when the social environment has been supportive of the basic needs and when the target individuals have been autonomously motivated.

For example, when elementary school teachers were more need supportive, their students were more intrinsically motivated and showed higher self-esteem; when instructors in a college course were more need supportive the students became more autonomously motivated for the course over the semester, understood the material better, and received higher grades in the course. And a study of medical students showed that when their instructors were more need supportive, the students internalized the course material more fully. In general, when the social context is more need supportive and people are more autonomously motivated for learning, they learn in a deeper more conceptual way, whereas, when the context is controlling or the learners are controlled in their motivation, they tend to do well at memorizing facts, but they show low levels of conceptual understanding (Ryan and Deci, 2009).

A study of employees in a work setting showed that when managers became more need supportive the employees were more satisfied with their jobs and more trusting of the company. A study of investment bankers showed that when

managers were more autonomy supportive, their employees performed better at their jobs and also showed better psychological well-being. These employees having higher autonomous causality orientations also contributed to their performing well and feeling good. In general, work settings that are more need supportive and workers who are more autonomously motivated have been found to yield more positive work outcomes (e.g., Baard et al., 2004).

In the domain of health care, for example, research has found that when physicians were need supportive, the patients were more autonomously motivated to take their medications and in turn showed greater medication adherence. Other research showed that when medical practitioners were more need supportive for diabetic patients, the patents' health improved (Ryan et al., 2008b).

In research on virtual worlds, results indicate that when players experience more satisfaction of the basic psychological needs while playing the games they are more intrinsically motivated for and more immersed in the games (Rigby and Ryan, 2011). They have also shown that much of the basis for players' aggression during or following game play is a function of their needs having been thwarted while playing.

Goals and Aspirations

The concept of goals has been perhaps the most common motivational concept in the psychological literature on motivation since the 1960s, when cognitive processes have been the central explanatory approach to psychology. Goals are outcomes that people value and hope to attain when engaging in particular behaviors. In SDT, although psychological needs is the most important explanatory concept, goals also have an important place. Specifically, SDT has focused on the degree to which people place value on what are called extrinsic life goals or aspirations, such as wealth, fame, and image, relative to intrinsic life goals such as personal growth, relationships, and community.

Research has shown that when people value the extrinsic aspirations more strongly than the intrinsic aspirations, they tend also to display poor psychological health, whereas when they value the intrinsic aspirations more strongly, they are psychologically healthier (Kasser and Ryan, 1996). These results have been consistently replicated in varied groups and cultures, and the explanation of the findings supported by SDT research is that the pursuit and attainments of the intrinsic goals of self-exploration, meaningful relationships, and community contributions tend to provide direct satisfaction of the basic psychological needs, whereas pursuit and attainment of the extrinsic goals of material possessions, social recognition, and attractive image are at best indirectly satisfying of the basic needs and may even be antagonistic to them.

Furthermore, research has shown that people tend to value the extrinsic aspirations when they have had a low level of basic psychological need satisfaction during their years as children, but they tend to value intrinsic aspirations when they have had a high level of basic satisfaction during those years (Kasser et al., 1995).

As well, studies found that if people's goals are manipulated experimentally, having intrinsic goals made salient led to better learning and performance than having extrinsic goals made salient. When, for example, business students who were learning about communications were told that it would help them learn about themselves, which is an intrinsic goal, their learning and performance was better than when the students were told that it would help them make more money, which is an extrinsic goal (Vansteenkiste et al., 2004).

Close Relationships

The concepts of SDT have also been used to examine close personal relationships such as best friends and romantic partners. Much of the SDT research has focused on the importance of autonomy in close relationships. Some theorists have argued that to have a satisfying close relationship people need to give up autonomy in service of the dyad, but SDT has argued that autonomy, as well as relatedness and competence, must be satisfied within a relationship in order for the relationship to be high quality and truly satisfying.

Studies have shown that indeed the degree to which people experience autonomy in a particular relationship predicts the degree of attachment security in that relationship. Across several relationships (e.g., mother, father, best friend, romantic partner) people experience considerable variability in the degree to which their need for autonomy is satisfied with different partners, and similarly they experience different degrees of attachment security. For each of the partners, autonomy need satisfaction directly predicted security of attachment in the relationship (La Guardia et al., 2000).

A different study examined best friend relationships and found that mutuality of providing autonomy support was important for satisfying friendships. In other words, when a person received autonomy support from a friend it contributed to the person's attachment security, emotional reliance, relationship satisfaction, and well-being, a set of findings that was true for each partner. Further, however, when a person gave autonomy support to the friend, not only did the friend benefit, but the person actually benefitted from the giving to the partner. So, both receiving autonomy support and giving autonomy support within a friendship benefits each partner in that relationship (Deci et al., 2006).

Summary

SDT is a motivational theory that differentiates between autonomous and controlled types of motivation and proposes that autonomous motivation leads to higher quality behavior and experience, especially for heuristic activities. It also differentiates between intrinsic and extrinsic aspirations and proposes that intrinsic aspirations are associated with greater well-being and better performance. Further, the theory specifies three basic psychological needs, those for autonomy, competence, and relatedness, which have been found to be universally essential for psychological health and well-being. Further, satisfaction of the basic needs not only promotes psychological health but also enhances intrinsic motivation, facilitates internalization of extrinsic motivation, supports the development of autonomous causality orientations, and strengthens intrinsic

relative to extrinsic aspirations. Across the domains of people's lives, the people are more optimally motivated, perform better, and feel healthier if their basic psychological needs are satisfied.

Self-Development in Childhood and Adolescence

Susan Harter, University of Denver, Denver, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The nature of children's and adolescents' concepts of self change with age, in large part due to cognitive-developmental changes. Young children's self-concepts are limited to specific, concrete representations (e.g., I can run fast, I know my numbers). In middle and later childhood, children's self-descriptions represent trait labels (e.g., I am smart because I do well in Social Studies, Language Arts, and Math). At adolescence, self-descriptions become increasingly abstract (e.g., I am intelligent, athletic). In addition to domain-specific self-concepts, the ability to evaluate one's overall worth as a person emerges in middle childhood. The level of such global self-esteem varies tremendously across children and is determined by how adequate they feel in domains of importance as well as the extent to which significant others (e.g., parents and peers) approve of them as a person. Low self-esteem is associated with many psychological liabilities including depressed affect, lack of energy, and hopelessness about the future. However, efforts to promote positive self-esteem can be problematic if they are based on unrealistically positive judgments, namely, overestimations of one's competencies. I review the debate about Self-Esteem Movement, which has taken place largely in our schools, which has been criticized for fostering unrealistic perceptions of children's competencies and, in collusion with some parents, a sense of entitlement. Moreover, one must consider cross-cultural differences in the nature of self-esteem, which are legion. Certain cultures (e.g., China) do not even have a term for self-esteem. Plus, instruments designed for Americans are often inappropriate, in terms of content and psychometric properties, leading to faulty interpretations.

Introduction

Beginning in the second year of life, toddlers begin to talk about themselves. With development, they come to understand that they possess various characteristics, some of which may be positive ('I am smart') and some of which may be negative ('I am unpopular'). Of particular interest is how the very nature of such self-evaluations changes with development as well as among individual children and adolescents across two basic evaluative categories: (1) domain-specific self-concepts, i.e., how one judges one's attributes in particular arenas, e.g., scholastic competence, social and (2) global self-esteem (for a complete treatment of self-development in childhood and adolescence, see Harter, 1999, 2012).

Developmental shifts in the nature of self-evaluations are driven by changes in the child's cognitive capabilities. Cognitive-developmental theory and findings (see Piaget, 1960,1963; Fischer, 1980) alert us to the fact that the young child is limited to very specific, concrete representations of self and others, for example, 'I know my ABCs' (see Damon and Hart, 1988; Harter, 1999). In middle to later childhood, the ability to form higher order concepts about one's attributes and abilities (e.g., 'I am smart') emerges. There are further cognitive advances at adolescence, allowing the teenager to form abstract concepts about the self that transcend concrete behavioral manifestations and higher order generalizations (e.g., 'I am intelligent').

Developmental Differences in Domain-Specific Self-Concepts

Domain-specific evaluative judgments are observed at every developmental level. However, the precise nature of these judgments varies with age. Five common domains in which children and adolescents make evaluative judgments about the self have been identified: scholastic competence, physical competence, social competence, behavioral conduct, and physical appearance (Harter, 1999). The types of statements vary, however, across age periods, early childhood, middle childhood, later childhood, and early, mid-, and late adolescence, in keeping with the cognitive abilities of each age period.

Early Childhood

Young children provide very concrete accounts of their capabilities, evaluating specific behaviors. Thus, they communicate how they know their ABCs, how they can run very fast, how they are nice to a particular friend, how they do not hit their brother or sister, and how they possess a specific physical feature such as pretty blond hair. Of particular interest in such accounts is the fact that the young child typically provides a litany of virtues, touting his or her positive skills and attributes. One cognitive limitation of this age period is that the young child cannot distinguish the wish to be competent from reality. As a result, they typically overestimate their abilities because they do not yet have the skills to evaluate themselves realistically. Another cognitive characteristic that contributes to potential distortions is the pervasiveness of all-or-none thinking. That is, evaluations are either all positive or all negative, but primarily, all positive.

Middle Childhood

As the child grows older, the ability to make higher order generalizations in evaluating his or her abilities and attributes emerges. The child may observe that he or she is good at sports, in general. This inference can further be justified in that the

child can describe his or her talent at several sports (e.g., good at soccer, basketball, and baseball). Thus, the higher order generalization represents a cognitive construction in which an overarching judgment (good at sports) is defined in terms of specific examples that warrant this conclusion. Similar processes allow the older child to conclude that he or she is smart (e.g., does well in math, science, and history). The structure of a higher order generalization about being well behaved could include such components as obeying parents, not getting into trouble, and trying to do what is right. A generalization concerning the ability to make friends may subsume accounts of having friends at school, making friends easily at camp, and developing friendships readily upon moving to a new neighborhood. The perception that one is good looking may be based on one's positive evaluation of one's face, hair, and body.

Later Childhood

During later childhood, all-or-none thinking diminishes and the aura of positivity fades. Thus, children do not typically think that they are all virtuous in every domain. The more common pattern is for them to feel more adequate in some domains than others. For example, one child may feel that he or she is good at schoolwork and is well behaved, whereas he or she is not that good at sports, does not think that he or she is good looking, and reports that it is hard to make friends. Another child may report the opposite pattern.

Contributing to this advance is the ability to engage in social comparison. Children can use comparisons with others as a barometer of the skills and attributes of the self. In contrast, the young child cannot simultaneously compare his or her attributes to the characteristics of another in order to detect similarities or differences that have implications for the self. Although the ability to utilize social comparison information for the purpose of self-evaluation represents a cognitive-developmental advance, it also ushers in new, potential liabilities. With the emergence of the ability to rank-order the performance of other children, all but the most capable children will necessarily fall short of excellence. Thus, the very ability and penchant to compare the self with others makes one's self-concept vulnerable, particularly if one does not measure up in domains that are highly valued. The more general effects of social comparison can be observed in findings revealing that domain-specific self-concepts become more negative during later childhood, compared to early childhood.

Early Adolescence

For the adolescent, there are further cognitive-developmental advances that alter the nature of domain-specific self-evaluations. Early adolescence brings with it the ability to create more abstract judgments about one's attributes and abilities. Thus, one no longer merely considers oneself to be good at sports but to be athletically talented. One is no longer merely smart but views the self more generally as intelligent, where successful academic performance, general problem-solving ability, and creativity might all be subsumed under the abstraction of intelligence. Abstractions may be constructed in the other domains. In the domain of behavioral conduct, there will be a shift from the perception that one is well behaved to a sense that one is a moral or principled person. In the domains of social competence and appearance, abstractions may take the form of perceptions that one is popular and physically attractive.

These illustrative examples all represent positive self-evaluations. However, during adolescence (as well as in later childhood), judgments about one's attributes will also involve negative self-evaluations. Thus, certain individuals may judge the self to be unattractive, unpopular, unprincipled, etc.

Mid-Adolescence

Of particular interest is the fact that when abstractions emerge, the adolescent typically does not have total control over these new acquisitions, just as when one is acquiring a new athletic skill (e.g., swinging a bat and maneuvering skis) one lacks a certain level of control. In the cognitive realm, such lack of control often leads to dramatic shifts in self-perceptions across situations or time. For example, the adolescent may conclude at one point in time that he or she is exceedingly popular but then, in the face of a minor social rebuff, may conclude that he or she is extremely unpopular. Moreover, adolescents develop multiple selves, how they are different in different role relationships, for example, cheerful with peers, depressed with parents, self-conscious on a date, etc. However, these vacillations and different selves cause distress, perceived psychological conflict, and confusion about just which is their 'true self' (see Harter, 2012).

Late Adolescence

Gradually, adolescents gain control over these self-relevant abstractions such that they become capable of more balanced and accurate self-representations (see Harter, 1999, 2012). They develop more advanced cognitive skills to deal with the confusion and the conflict between their multiple selves. Two strategies have been documented in the author's own work. As adolescents advance to more mature levels of cognitive development, they develop higher levels of abstractions that can integrate the seeming contradictions of the previous period. For example, the realizations that they are depressed with parents but cheerful with friends can be subsumed under the more advanced abstraction that they are 'moody,' thus integrating and justifying what were previously inconsistent self-perceptions. Second, older adolescents normalize what were former contradictions, describing how it would be 'weird' to be the same with your mother as you are on a date, or with friends at a ball game (see Harter, 2012).

Global Self-Esteem

The ability to evaluate one's worth as a person also undergoes developmental change. The young child simply is incapable, cognitively, of developing the verbal concept of his or her value as a person. This ability emerges at the approximate age of

8 years. However, young children exude a sense of value or worth in their behavior. The primary behavioral manifestations involve displays of confidence, independence, mastery attempts, and exploration (see Harter, 1999, 2012). Thus, behaviors that communicate to others that children are sure of themselves are manifestations of high self-esteem in early childhood.

At about the third grade, children begin to develop the concept that they like, or do not like, the kind of person they are (Harter, 1999; Rosenberg, 1979). Thus, they can respond to general items asking them to rate the extent to which they are pleased with themselves, like who they are, and think they are fine, as a person. Here, the shift reflects the emergence of an ability to construct a higher order generalization about the self. This type of concept can be built upon perceptions that one has a number of specific qualities, for example, that one is competent, well behaved, attractive, etc. It can also be built upon the observation that significant others are approving and supportive, for example, parents, peers, and teachers, think highly of the self. This process is greatly influenced by advances in the child's ability to take the perspective of significant others (Selman, 1980). During adolescence, one's evaluation of one's global worth as a person may be further elaborated, drawing upon more domains and sources of approval, and will also become more abstract. Thus, adolescents can directly acknowledge that they have high or low self-esteem, as a general abstraction about the self.

Individual Differences in Domain-Specific Self-Concepts as Well as Global Self-Esteem

Although there are predictable cognitively based developmental changes in the nature of how most children and adolescents describe and evaluate themselves, there are striking individual differences in how positively or negatively the self is evaluated. Moreover, one observes different profiles of children's perceptions of their competence or adequacy across the various self-concept domains, in that children evaluate themselves differently across domains. Consider the profiles of four different children. One child, Child A, may feel very good about her scholastic performance, although this is in sharp contrast to her opinion of her athletic ability, where she evaluates herself quite poorly. Socially she feels reasonably well accepted by her peers. In addition, she considers herself to be well behaved. Her feelings about her appearance, however, are relatively negative. Child A also reports very high self-esteem. Another child, Child B, has a very different configuration of scores. This is a boy who feels very incompetent when it comes to schoolwork. However, he considers himself to be very competent, athletically, and feels well received by peers. He judges his behavioral conduct to be less commendable. In contrast, he thinks he is relatively good-looking. Like Child A, he also reports high self-esteem.

Other profiles are exemplified by Child C and Child D, neither of whom feel good about themselves scholastically or athletically. They evaluate themselves much more positively in the domains of social acceptance, conduct, and physical appearance. In fact, their profiles are quite similar to each other across the five specific domains. However, judgments of their self-esteem are extremely different. Child C has very high self-esteem, whereas Child D has very low self-esteem. This raises a puzzling question: how can two children look so similar with regard to their domain-specific self-concepts but evaluate their global self-esteem so differently? The author turns to this issue next, in examining the causes of global self-esteem.

The Causes of Children's Level of Self-Esteem

The understanding of the antecedents of global self-esteem has been greatly aided by the formulations of two historical scholars of the self, William James (1892) and Charles Horton Cooley (1902). Each suggested rather different pathways to self-esteem, defined as an overall evaluation of one's worth as a person (see reviews by Harter, 1999, 2012; Rosenberg, 1979). James focused on how the individual assessed his or her competence in domains where one had aspirations to succeed. Cooley focused on the salience of the opinions that others held about the self, opinions that one incorporated into one's global sense of self (*see* Self: History of the Concept).

Competence–Adequacy in Domains of Importance

For James, global self-esteem derived from the evaluations of one's sense of competence or adequacy in the various domains of one's life relative to how important it was to be successful in these domains. Thus, if one feels one is successful in domains deemed important, high self-esteem will result. Conversely, if one falls short of one's goal in domains where one has aspirations to be successful, one will experience low self-esteem. One does not, therefore, have to be a superstar in every domain to have high self-esteem. Rather, one only needs to feel adequate or competent in those areas judged to be important. Thus, a child may evaluate himself or herself as unathletic; however, if athletic prowess is not an aspiration, then self-esteem will not be negatively affected. That is, the high self-esteem individual can discount the importance of areas in which one does not feel successful.

The author has directly examined this explanation in research studies by asking children to rate how important it is for them to be successful (Harter, 1999). The findings reveal that high self-esteem individuals feel competent in domains they rate as important. Low self-esteem individuals report that areas in which they are unsuccessful are still very important to them. Thus, the discrepancy between high importance and perceptions of inadequacy contribute to low self-esteem. In contrast, the congruence between importance and feelings of success leads to higher self esteem.

Incorporation of the Opinions of Significant Others

Another important factor influencing self-esteem can be derived from the writings of Cooley (1902) who metaphorically made reference to the 'looking-glass self.'

According to this formulation, significant others (e.g., parents and peers) were social mirrors into which one gazed in order to determine what they thought of the self. Thus, in evaluating the self, one would adopt what one felt were the judgments of these others whose opinions were considered important. Thus, the approval, support, or positive regard from significant others became a critical source of one's own sense of worth as a person. For example, children who receive approval from parents and peers report much higher self-esteem than children who experience disapproval from parents and peers.

The author's findings (Harter, 1999, 2012) reveal that both these factors, competence in domains of importance and the perceived support of significant others, combine to influence a child's or adolescent's self-esteem. Thus, those who feel competent in domains of importance and who also report high support, rate themselves as having the highest self-esteem. Those who feel inadequate in domains deemed important and who also report low levels of support rate themselves as having the lowest self-esteem.

Cross-Cultural Considerations

Globalization and the proliferation of psychological research on the international scene is a welcome new trend. However, one must appreciate that there are clear differences between Western and Eastern conceptions that much be recognized, before Westerners encourage Eastern cultures to embrace Western frameworks, paradigms, and instruments (Harter, 2012). Clearly, self-esteem is a value touted by Americans, as witnessed by the many attempts to protect and enhance it (Harter, 2012; Leary, 2004). However, high self-esteem, based on individual accomplishments, is not revered as a psychological commodity in most Eastern cultures (see Harter, 2012). In fact, in some languages, namely, Chinese and Japanese, there is no equivalent term for 'self-esteem.' Self-esteem is simply not a core value and therefore is not represented or codified in their respective languages.

This leads to numerous problems when instruments designed for Americans are administered in many other countries (see Harter, 2012). First, the content may not be appropriate, meaning at the domain or item level. Most noticeable is that self-esteem items do not resonate with such populations. As a result, this interferes with the psychometric properties in that American instruments administered in such countries lack reliability and validity, and the factor structures do not hold up. Question formats such as the one employed in our own instruments pull for social comparison, which is frowned upon in many countries, leading to lower scores than would be anticipated given objective data about levels of achievement and competencies in certain cultures. See Harter (2012) where these different issues are addressed in more detail. There, the author urges that those in different cultures take stock of these problems and perhaps initially designed interview questions to address their specific research questions and hypotheses that are more culturally sensitive and will lead to more meaningful findings.

To Raise or Not to Raise Self-Esteem within both Society and Our Schools

For two decades, considerable debate and controversy has surrounded this question. Initiatives have been proposed to raise self-esteem at the national and state levels, as a cure-all for many societal ills. Parallel interventions at the classroom level have been urged by some educators who presume that self-esteem enhancement should motivate students to attain higher levels of academic achievement. The initiative adopted by the State of California, in 1990, reflects one of the most ambitious efforts to tackle this issue at a legislative level (California Task Force to Promote Self-Esteem and Personal Responsibility, 1990). This particular initiative became a public marker of the 'Self-Esteem Movement.' Its message was also a subtext in the playbooks of many educators.

California state legislators expressed their conviction that by raising the self-esteem of its citizenry, many social ills would be significantly reduced, for example, crime, teen pregnancy, delinquency, drug abuse, and school underachievement. Such a widespread intervention would lead to better societal, as well as personal, outcomes. The California initiative vaulted the topic of self-esteem into the national limelight, as the media scrambled to cover the frenzied efforts to alter self-perceptions in the service of the greater cultural good. Swann (1996) likens the quest for high self-esteem to the search for the Holy Grail, pointing to the dizzying array of programs that proliferated. Unfortunately, these efforts did not have their intended effects, based upon very disappointing findings that did not produce the desired outcomes. Self-esteem, particularly if it was unrealistically enhanced, did not represent the anticipated panacea that would cure our social ills (see Eccles and Roeser, 2009).

How the self-esteem movement played out on the stage of America's classrooms, as an educational microcosm of society, is of particular relevance in terms of its implications for the youth. A major focus of many educational interventions has been the enhancement of self-esteem, given the argument that student achievement would improve, as a result. These contentions have fueled an intense debate that is reflected within the educational and psychological literature (see review in Harter, 2012). Proponents have touted the advantages of enhanced self-esteem, whereas opponents have vociferously argued that such efforts are not only misguided and useless, at best, but destructive, at worst. What are the primary arguments, pro and con?

The claims of the proponents are perhaps the most straightforward, given the belief and insistence that raising the self-esteem of students will produce higher levels of achievement and foster academic success, primarily measured by grades and test scores (see Tice and Gailliot, 2006; for thoughtful reviews of the dispute).

Those who believe in the value of enhancing self-esteem among students first argue that while admittedly modest, the correlation between these two constructs is sufficient to warrant educational intervention. Second, these proponents also contend that the enhancement of self-esteem will

produce educational benefits, that is, global perceptions of one's worth as a person act causally to promote gains in academic achievement.

Opponents of educational interventions first point out that the magnitude of the correlation between self-esteem and academic achievements is relatively trivial and thus without serious implications. Second, they challenge the presumed directionality of effects. That is, although the two constructs may bear a modest correlation to one another, it is just as likely that successful achievement in the classroom (as indexed by good grades and high standardized test scores) represents the cause of higher self-esteem, not the effect. These are the general arguments that define each position. Next, the author turns to the more nuanced considerations.

A major concern addressed by many opponents is that seeking to boost self-esteem can artificially destroy any incentives for students to devote effort toward scholastic goals (Tice and Gailliot, 2006), particularly if self-evaluations are unrealistic. Inflated self-esteem provides no incentive for self-improvement. Moreover, the practice of inviting students to make unconfirmed self-affirmations as to their worth ('I am smart,' 'I am awesome,' 'I am special') do not appear to be effective.

Damon (1995) was also among the first to be critical of what he considered an overemphasis by educators on promoting high self-esteem, particularly when these efforts lead to an inflated sense of one's self-worth. Damon has viewed such efforts as not only misguided but potentially detrimental, arguing that they divert educators from the active teaching of skills and deprive students of the thrill that results from personal accomplishment. It has been Damon's contention that self-esteem has become an overrated commodity and that the effusive praise that parents and teachers heap on children to make them feel good about themselves is often met with suspicion by the children themselves. Moreover, it interferes with their attention to the goal of building specific skills in the service of genuine achievement. It does a grave educational injustice to encourage children to think well of themselves without having earned it. Cote (2009) has joined the ranks of opponents, decrying the 'cult of self-esteem' that has gripped schools in this country.

'Feel-good activities,' a mainstay of many of the self-esteem interventions to emerge in the 1980s, have produced few gains, despite the widespread commercial packaging of programs designed to enhance self-esteem. They demand that teachers suspend corrective feedback and remove challenging material, 'dumbing down' the curriculum (Damon, 1995). Such activities divorce self-esteem from palpable achievements that result from realistic attributions to the student's personal effort. As a result, they confound self-esteem with egocentrism, narcissism, arrogance, conceit, and self-delusion (see Harter, 2012). That said, proponents of these packaged programs claim that the self-affirming affective exercises and techniques will extend, not only to heightened school performance, but to broader societal goals to help curb such teenage social ills as pregnancy, drug use, and delinquency. However, there is little evidence to warrant these claims (see Covington, 2006). Moreover, given my own experience in the schools over the years, many teachers who were forced to administer what they called touchy-feely exercises complained that this was not their job definition, rendering them less than effective if they attempted to mouth the self-esteem mantra.

Furthermore, the goal of self-enhancement strategies, for its own sake, interferes with the educational goals of learning and mastery. As Covington (2006) observes, enhanced achievement is more likely if children are motivated to learn for the sake of learning, to stimulate their own curiosity, to challenge themselves, and to set personal goals that involve skill improvement. If the reasons behind school performance are more self-promotional and defensive in nature, for example, striving to succeed in order to avoid failure with its implication that one is incompetent, academic motivation will wane because of the fear that one cannot succeed.

Perhaps one of the strongest and most vocal opponents of self-esteem enhancement programs within the school system is Baumeister and colleagues (Baumeister, 1996; Baumeister et al., 2003). Baumeister's devastating critique is captured by this assertion: "At worst, the pursuit of high self-esteem is a foolish, wasteful, and self-destructive enterprise that may end up doing more harm than good" (Baumeister, 1996: p. 120). What is the basis for his contentions?

To begin with, Baumeister is critical of the California initiative to promote self-esteem, which professed to represent a social vaccine to cure or hopefully inoculate citizens against the evils of crime, violence, substance abuse, teen pregnancy, child abuse, chronic welfare dependency, and educational failure. He rightfully asserts, consistent with the considerable evidence on narcissism, that for many in this country, self-esteem is already inflated.

We seem to be revisiting an earlier movement, from the 1960s and 1970s, what the author has called the Camelot era of self-esteem interventions, which invoked simplistic attempts to enhance self-esteem that were unsuccessful. These urged general self-affirmations (e.g., "I'm OK, you're OK" messages) and affective feel-good exercises that were designed to impact self-esteem directly. The contemporary analog can be observed among educators, coaches, and parents who have fallen prey to the 'good job!' mantra. Children and adolescents are lavishly and indiscriminately praised for their efforts, independent of whether they warrant such positive feedback.

Recent findings (reviewed in Harter, 2012) reveal that narcissism among the youth has systematically increased over the past three decades, given that society, in general, and schools, in particular, have both perpetuated messages and practices that promote self-enhancement, self-serving biases, and a sense of entitlement. Affirmations of 'specialness' and educational practices such as grade inflation and 'dumbing down' the curriculum prompt unrealistic views of competence and contribute to narcissistic self-promotion. In May of 2012, in a risky and courageous high school graduation speech, the speaker shocked students and outraged parents by his blatant contention that "you students are not special!" It was a wake-up call that caught the attention of the national media and reactions went viral. Thus, the bottom line is

that our educational system and child-rearing practices should cultivate behaviors that produce self-views that are both realistic (that is, based on objective evidence) and adaptive (that is, promote activities that predict long-term adjustment to the demands of society).

Conclusions

Two types of self-representations that can be observed in children and adolescents were distinguished, evaluative judgments of competence or adequacy in specific domains and the global evaluation of one's worth as a person, namely, overall self-esteem. Each of these undergoes developmental change based on age-related cognitive advances. In addition, older children and adolescents vary tremendously with regard to whether self-evaluations are positive or negative. Within a given individual, there will be a profile of self-evaluations, some of which are more positive and some more negative. More positive self-concepts in domains considered important, as well as approval from significant others, will lead to high self-esteem. Conversely, negative self-concepts in domains considered important, coupled with lack of approval from significant others, will result in low self-esteem. Self-esteem is particularly important since it is associated with very important outcomes or consequences. Perhaps the most well-documented consequence of low self-esteem is depression. Children and adolescents (as well as adults) with the constellation of causes leading to low self-esteem will invariably report that they feel depressed, emotionally, and are hopeless about their futures; the most seriously depressed consider suicide. Thus, it is critical that one intervenes for those experiencing low self-esteem (see suggestions in Harter, 1999).

Positive self-esteem can be a psychological commodity, a resource that is important for us to foster in our children and adolescents if we want them to lead productive and happy lives. However, unrealistically inflated positive views of one's competencies and worth as a person can also compromise one's personal growth. It can lead to self-aggrandizing tendencies that can merge into narcissism, which can eventually alienate others and lead to blame and hostile behaviors (see Harter, 2012, 2012). Thus, our responsibility should be to foster realistic self-perceptions and provide support to encourage children and adolescents to develop the necessary skills toward that goal.

Self-Directed Care and Individual Budgets for Older People: Lessons from the UK

Jill Manthorpe, King's College London, London, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Policy ambitions to put older people at the center of their own care are being developed internationally. These enable people to express their choices in, and control over, the support they require to make life good. This article outlines the common approaches to this trend and summarizes evidence about the implications of personal budgets, cash for counseling, consumer-directed care, and self-directed support. It discusses the evidence base related to older people as consumers and the implementation of schemes that have been evaluated. The article debates these developments in the context of social science theories.

Introduction and Background

One of the major changes to the care and support of older people in the developed world is that of 'cash for care' schemes or personal allocations of funding to meet care needs (Ungerson and Yeandle, 2007). These are affecting the lives of many disabled older people and their family carers. The changes introduced have been greatly influenced by disability movements and disability politics. They are reforming the social systems of 'care for the aged' and have influenced the social science discipline of gerontology by reminding it of the linkages to disability theory, practice, and politics.

This article draws on the international literature (see Ottmann et al., 2013; Rummery, 2011; Alakeson, 2010) but particularly the current story of the transformation of adult social services in England and Scotland, to illustrate the potential for the social and behavioral sciences to make sense of this change. The aims of the transformation to personal budgets or self-directed support (SDS) (the terms used in the UK to cover 'cash for care' schemes) are to broaden choice and control for people using social care services – generally assistance with activities of daily living (DH, 2008). Overall, it is referred to in England as the policy of personalization. The objective is to improve outcomes for older people and their carers (family caregivers). Central government in England has used the overarching term personalization to direct local government to transform its assessment, allocation systems, service provision, monitoring, and reviews of people needing care and support (HM Government, 2007). In Scotland, the term self-directed support (SDS) is more commonly employed (Scottish Government, 2013). Terms such as consumer-directed care are used to cover similar changes in other countries such as Australia and the United States (US) (Ottmann et al., 2013).

Under the United Kingdom (UK) welfare state system, disabled adults or others in need of care and support are entitled to assistance from local authorities if they meet eligibility criteria around need and risk although they must pay a means-tested contribution if their income or resources are above a minimum level. The essence of the change being made by the policy of personalization is that individuals are encouraged to be more involved in assessing their needs for support; that they are told how much money they are likely to be allocated to meet these needs, and that they can choose how to meet their needs. In early pilots of this approach this money was referred to as an individual budget. At the time of writing in many areas it is now being termed a personal budget or Direct Payment. In light of the sums available to them, older people and other eligible adults devise a support plan to meet their needs, deploying this in a variety of ways, including taking this money in the form of a Direct Payment (cash paid to the person or their proxy), or as a combination of this with local authority commissioned services, or using it to draw up a contract themselves with an organization or individual that provides care as part of its business. The person's support plan has to be agreed with the local authority (often by social work professionals) and is reviewed. As this article reports, there is concern that positive outcomes for older people may be small in scale or not widespread, and some of these issues are explored in this article.

The Evidence Base

These developments rest on evidence that existing services and systems do not meet people's needs effectively, particularly older people who may have combinations of need and frailty that change frequently and unpredictably (Feltoe and Orellana, 2013). Older people report that some social care services funded or provided by local authorities (such as care at home or day-care center) do too little to meet their needs and often arrive too late, offer limited choice, seem paternalistic in nature, and reduce rather than promote independence. Older people are less likely to actively participate in assessment and more likely to underestimate their needs than other disabled adults. The 'lottery' of provision and support reported (Manthorpe et al., 2008) suggests current systems do not meet individuals' needs equitably and agism is often seen to underpin such inequity.

Not surprisingly, given the changes required to set in place the new system of personal budgets, there have been widespread calls for training of frontline staff. Moreover, given the extent of change a number of training initiatives, information events and written and electronic materials are being developed to inform older people of their options, to tell them about the new system and to describe the responsibilities accompanying the exercise of choice and control. This may be seen as part of the 'responsibilization' of citizens under which people have

 http://dx.doi.org/10.1016/B978-0-08-097086-8.28044-6

both rights and responsibilities, which include the taking on of responsibilities previously assumed by the state or professionals. Coproduction is another term used to describe this aspiration for a change in professional and client (user) dynamics (Needham and Carr, 2009).

In parallel, the risks of personal budgets have been highlighted by those with an interest in avoiding the abuse and neglect of older people. The discovery or social construction of the social problem of 'elder abuse' has been another key development in social gerontology in the past few decades (Dixon et al., 2010). Social science theories have also been used to describe the ways in which risk is constructed and can be managed proportionally (Manthorpe and Moriarty, 2010). Personal budgets have been described as 'inherently risky' by some professionals who believe that some older people, for example, with dementia, are open to exploitation in new systems where monitoring and review are not sufficiently sophisticated to be able to identify and respond to possible risks of harm or abuse (Manthorpe and Samsi, 2012).

Evidence and Evaluations

These developments and these theoretical perspectives have been informed by social science evaluations. A major UK study used a randomized control trial (RCT) methodology, meaning that the quality of the evidence is good. In 2005 the English Department of Health (DH) commissioned a wide-ranging evaluation of the 13 individual budget (IB) pilot projects (the Individual Budgets Evaluation Network – IBSEN) (see Glendinning et al., 2008). This evaluation investigated the outcomes, costs and cost-effectiveness of IBs compared with conventional methods of funding, commissioning and service delivery. Comparisons were made for all user groups pooled together and for individual user groups. They were based on data collected 6 months after individuals started receiving their IBs and on in-depth interviews with a subsample roughly 2 months after they had decided to accept an IB.

IBSEN's findings about IBs and *older people* were different from those for other user groups (people under retirement age with learning disabilities; physical disabilities or mental health problems) (see Moran et al., 2013). Older people:

- Were significantly less likely than people in other user groups to report higher aspirations as a result of their experience of the IB process.
- Reported lower psychological well-being than those in the comparison group. (There was some complication in the interpretation of this finding, because it was influenced by whether the interviews were completed by proxy respondents rather than the older people themselves.)
- Provided evidence that there were no significant cost differences between the IB and comparison groups, both for the pooled sample and for older people separately. Across all user groups combined there was some indication of higher use and higher costs of health care services by people in the IB group relative to the comparison group, and also higher care coordinator (care manager/social worker) costs.
- Provided little evidence of cost-effectiveness differences between IBs and standard or traditional support arrangements for older people when concentrating on social care outcomes as the measure of effectiveness. When looking at psychological well-being, standard support arrangements were marginally more cost-effective than IBs.
- Reported themselves in interview they generally did not want the 'additional burden' of planning and managing their own support, with responsibilities for managing a budget, making new arrangements, and managing the risks associated with directly employing care workers rather than having them provided by an agency or local authority.

One hypothesis developed to explain these differences was that it might be too early for older people to have developed the confidence to assume the greater control that comes with holding an IB. Practitioners such as social workers reported that older people had reservations and concerns about IB payments, namely lack of confidence; and fluctuating, poor health and progressive disabilities that would perhaps require multiple adjustments. Another hypothesis was that local authorities might not have had the opportunity within the short timeframe of the IB pilots to implement arrangements suiting older people. For example, many older people receiving IBs opted for care-managed 'virtual budgets' (whereby older people did not manage any money themselves and the arrangements of their support plan were in the hands of a social worker or care manager) and thereby the scope for them to feel in control might have been limited. Practitioners noted that older people often called for help in crisis; and support had to be put in place immediately; not being developed in conjunction with the older person as much as it ideally could have been. A third hypothesis was that the lower average levels of money received as 'virtual' budget or as a Direct Payment by older people, and the predominant use of IBs to fund personal care, offered fewer opportunities to develop tailored support that could impact positively on outcomes. In other words, the inherent agism of support for older disabled people was thrown into sharp relief when it was possible to compare allocations for younger and older disabled people.

However, other evidence has given cause for concern about the experiences of older people while personal budgets are developing nationwide. These highlighted the need to ensure that older people are not disadvantaged by the very policies intended to foster better care and lead to better outcomes. Woolham and Benton (2012), for example, concluded from their detailed study of the impact and outcomes of personal budgets (termed SDS) in the county of Northamptonshire that there were limited benefits and great costs for older people of these new arrangements. Older people receiving SDS in their study were less likely to feel in control; to feel empowered; to feel they were getting the right type of support than other age groups; to feel they had the final say about how the money should be spent and displayed less evidence of positive impact. Overall costs of SDS were higher for all, especially for older people. In the context of evidence-based practice, these studies need to be set alongside powerful personal accounts of the benefits of personal budgets for some older people (see for example Newbronner et al., 2011; Feltoe and Orellana, 2013). A recent systematic review found low-quality evidence for consumer-directed care and notes that while it appears to increase satisfaction with care and community service use it has little effect on clinical outcomes for older people (Low et al., 2011).

Implementation

Personalization has provided great scope for social scientists to research services for older people and has increased understanding of lived experience, care dynamics, and service outcomes. Studies have included major national trials (see Glendinning et al., 2008), local evaluations (Woolham and Benton, 2012), and qualitative explorations (Newbronner et al., 2011). A range of studies has also focused on implementation of government policy and used personalization of an example of complexity and nonlinear development. In particular, implementation research has pointed to the blurring of exhortation and guidance:

> Implementation of personalisation in its broadest sense has proven difficult to measure and record in practice. There are some activities and targets which have been used to indicate that a local authority or provider is taking a personalised approach to provision, but we know that it is as much about culture change and attitude of staff as about process and procedure. Policy documents related to personalisation in social care are, therefore, a mixture of description of the vision of personalisation combined with gentle persuasion aimed at local authorities and providers to implement change.
>
> Feltoe and Orellana, 2013: p. 12

Microlevel Understandings

It is not surprising that mixed views are emerging. Social care support for older people reflects the circumstances in which they first encounter publicly funded social care, often at times of crisis or change. In this section microperspectives are used to explore how older people with experiences of IBs (now personal budgets in the main in England and SDS in Scotland) are able to exercise choice by 'managing the money' themselves, rather than having a budget managed by the local authority (for details of this see Feltoe and Orellana, 2013). **Box 1**, for example, sets out what an older person is able to spend their personal budget on in one local authority area and displays not only the extent but also the limits of choice. It is important to understand the meanings behind such conditionality; in Australia, for example, the prohibition on employing family or friends may have its advantages (minimizing role blurring) but also disadvantages (reducing choice) (Low et al., 2012). In the US evidence from qualitative interviews suggests that poor older people may see this economic transaction – employing family members – as a reciprocal activity and that they value the enhanced relationship (San Antonio et al., 2006).

Box 1 Local stipulations for a personal budget (anonymized local authority)

A person managing a budget is required to:

- set up a separate bank account so that the personal budget can be paid to them by the local authority every 4 weeks;
- be responsible for paying for their support, depending on what support or services are arranged;
- make all payments using check or direct debit. No cash transactions are to be made with the personal budget money;
- spend their money on a flexible basis and therefore need to keep track of how their money is spent; and
- keep a record of how their money is spent, and are expected to keep receipts and bank statements.

The social science literature on choice as applied to the subject of personal budgets was summarized by Stevens et al. (2011). As they noted, if people with social care needs have sufficient cash to enable them to exercise choices over their care and support, this theoretically alters the power dynamics of relationships between older people, professionals, and the organizations in which they work, in relation to needs and how to meet them. It is further argued that increasing individuals' choice over the services they use or the people they employ at microlevel may affect public decisions about priorities and resource allocation (macrolevel). However, they cautioned that a focus on increasing choice at the expense of other concerns, such as variable levels of support for different groups and decreasing the range of affordable options to meet needs of different kinds ran the risk of increasing inequity.

The Benefits of Personal Budgets

Nonetheless older people generally see personal budgets as giving them more freedom of choice and control, enabling them to get support when they want it; and sometimes enabling this support to be more flexible and creative (Moran et al., 2013). They also appreciate knowing what money is available. In contrast, practitioners have observed that while these might be the aspirations of personal budgets, they are also a way to control costs for the local authority. One key change is the move from traditional day center or day services care to 'day opportunities' which are hard to define and assess, and may be laden with value judgments (Manthorpe and Moriarty, 2013).

Sadly, the social sciences have not generally been greatly interested in researching 'low-level' support for older people so one difficulty in relation to social care services of all types is that reports covering usage and user experiences are often small scale and the context of the service is not always clearly described, making it difficult to know what is offered at the service, what is used and by whom, and the outcomes intended, achieved or unachieved. Day services exemplify this. Some day care is described as 'low level' and therefore comparisons with other day-care centers would need to ensure this was taken into account and whether 'low level' describes the needs of older people using the service or the support provided. Patterns of activities or therapy and take-up may vary. Few studies enable us to see the older people using day-care services in the context of other parts of their lives; so we do not always know whether the older person receives support from other parts of the social care system or from family networks, for example. Small ethnographic studies are valuable but they cannot make up for this wider lack of knowledge about service aims, costs, and systems. The impact of this lack of evidence is that the outcomes of personal budgets are difficult to compare to 'treatment as usual.'

Maximizing the Skills of Older People to Manage Their Personal Budget

At microlevel, much depends on older people's familiarity with financial matters generally and if they are accustomed to managing their incomes and savings, if any, should they take on financial management. If people already hold bank accounts then dealing with a new form of credit and debit is likely to be easier than for those unused to managing their money in such ways, such as people living more 'cash in hand.' This may be class-related since it also extends to people's habits in meeting bills and their other financial obligations. One of the problems with mild cognitive impairment or a dementia and other frailty is that older people may find money management more difficult. The social and behavioral sciences are beginning to tell us more about what aspects of financial management are affected by cognitive impairment such as memory, calculation, and estimates of risk (Manthorpe and Samsi, 2012).

Some older people in touch with social care services want to know the details of the rules of personal budgets, such as how they can be used, what they can be used on, and how they may increase or decrease as circumstances change. In England there are numerous examples of people paying for personal care and housework (particularly cleaning), respite breaks, food, transport, ironing, travel, household repairs, computer packages, and lessons (see Newbronner et al., 2011; Feltoe and Orellana, 2013). **Box 2** sets out the guidance provided to older people by one local authority.

On the other hand, some older people have complained that they are not permitted to use their personal budget as they choose. **Box 3** sets out the limits placed by one local authority.

Much of this knowledge touches upon the need for financial skills; particularly organizational abilities; not only to run a financial system generally but also being able to manage change and the unexpected. Numeracy skills are not only important in terms of Direct Payment management but also as a way of knowing and understanding the processes agreed with the local authority. Being able to manage budgets, records, prioritize and spread expenditure resonates with the theory of 'responsibilization' or of 'coproduction' (Needham and Carr, 2009). The areas requiring financial capacity or competence are listed below, and **Box 4** identifies specific elements needed to engage with banking services:

- How to save money each month to put toward something.
- Costs – e.g., what is a 'reasonable' cost of a care worker?
- What expenses come out each month of the Personal Budget?
- Knowing incoming and outgoing amounts every month.
- Having a simple table (spreadsheet) to outline the year's costings and a simple calculator/formula to help social workers see how a personal budget would be spent.
- Providing tips/advice/tools for effective record keeping.
- Tools to assist with this practically – calculator, computer, and so on.

Making Personal Budget Systems Easier for Older People

Not surprisingly, there have been concerns that older people find such systems difficult and the recent years have seen developments to improve access to personal budgets and better support for older people in particular. Evidence from one long-standing state Cash and Counseling Demonstration and Evaluation (CCDE) (Arkansas) program in the US is that building in flexibility and support structures, such as representatives,

Box 2 How can I use my Personal Budget?

Your Personal Budget must be used to meet your needs, as agreed in your Support Plan. Some examples of how you can use your Personal Budget are:

- helping you with personal care, such as bathing and getting dressed
- helping you with day-to-day tasks at home
- helping you get out and about
- helping you to find and pay for day activities, such as a course or a club
- getting help to find work
- paying for equipment such as a computer, which may help you to be more independent
- anything else that helps you achieve what is expected in your Support Plan.

Source: London local authority, 2009.

Box 3 Stipulations around the use of Personal Budget: users are *not* permitted to

- pay for anything illegal
- gamble
- buy alcohol or food
- pay a family member who lives with you to care for you
- pay for anything that the National Health Service (NHS) would pay for
- pay for care outside the UK for longer than 4 weeks (other than in exceptional circumstances)
- pay utility (e.g., fuel) bills, rent or mortgage

Please note, other sources of funding should be explored prior to the allocation of a Personal Budget.

Source: London local authority, 2009.

Box 4 Understanding banking: necessary competencies

- Choosing the right account for the personal budget and understanding it.
- Being aware of the costs of running the account, bank charges, overdraft charges, operations of standing orders, direct debits, etc.
- Arranging the user's contribution to budget/bank accounts.
- Understanding of the time frames around any delays in paying money in – allow time before withdrawal.
- Understanding of the processes and implications of telephone/internet banking (systems for access to account).
- Understanding bank statements, arranging for them to be in paper/large print.
- Rules for changing account.
- Safeguarding against fraud.

consultants, and fiscal intermediaries, safeguards consumers and program funding alike.

One development is greater publicity for positive and personal examples. Recent evidence on day opportunities among older people using personal budgets (funded by local authorities) offers some illustrations of the ways in which people may use such money to choose activities that are tailored to their identity or interests. Personal budgets and self-directed support may offer increased opportunities for people to have greater choice in terms of how they spend their time and with whom. However, it will be important to assess whether closures of traditional day services have a differential impact on people, especially those with very severe disabilities and their carers who may find it hard to access the day opportunities of mainstream and specialist social and leisure activities even with very intensive support.

To provide greater confidence for older people and those supporting them that there are options for great choice and control that will improve rather than diminish their quality of life; 'theories of organizational change' (see Iles and Sutherland, 2001) provide helpful perspectives, particularly those suggesting that thinking and doing are mutually informative. First, the calls for a safety net of support need thought as well as action so that professionals can respond to the immediate concerns, crises, and breakdowns of arrangements that are likely to occur among older people, their support networks and social care providers. Community development approaches may foster the building of close-knit communities but by their very nature these are locally determined and more informal than organized. While the importance of these has been discussed in relation to older people in rural areas (Manthorpe and Stevens, 2009), where care workers may live far from their employers (Dale and Brown, 2005), such concerns are general in nature.

Greater nuances in the reported experiences of older people receiving personal budgets also highlight the heterogeneity of older people. Some older people do not report personal budgets as transformational, as expressed by the respondents in Woolham and Benton's study (2012) some aspects may be preferable but some compromises may be necessary. A mixed picture may seem more authentic to older people and their families than accumulations of resolutely 'transformed lives.' It may help to make sense of what older people report to be 'hassle' around new arrangements, and their instincts that, of all age groups, they do not consider all change as an improvement, nor does it happen without costs or some negative outcomes.

A third theory that may help to understand personalization in practice relates to the professional 'gaze' or surveillance of older people. In service terminology, this refers to the type and level of monitoring around personal budgets and what to do if 'misuse' occurs. It is evident that practitioners have regretted the missed opportunities to scrutinize the tensions of competing policy 'agendas' around choice and control with safeguarding people from abuse under the banner of personalization (Manthorpe et al., 2009; Hunter et al., 2012). Older people are not used to scrutiny in respect of disability benefits and may associate closer monitoring with the reinvention of the 'snoopers' of the Poor Law system. While debates about surveillance in old age have often concentrated on it in institutional settings (Kenner, 2008) personalization throws up potentially new forms of regulation and self-regulation. This includes the 'responsibilization' thesis of becoming employers with the legalities of checks and controls that this status incurs.

These matters, of safeguarding and of monitoring, cast light on the new relationships being forged between older people and social workers (and between older people and the state). On the one hand, personal budgets are likely to intensify consumer behavior and consumer identities among some older people and their families (see Stevens et al., 2011) and consumerism in pensions (Mann, 2006) can be seen as a forerunner of personalization of care and support. Systems of resource allocation will be clarified and this may lead to an increase in numbers of older people and their families feeling that it is worth the 'hassle' or trouble of engaging with public forms of social care. This form of empowerment will make demands upon practitioners who have often seen themselves as possible advocates for older people or have acted as gatekeepers to resources.

Finally, the need for 'responsibilization' and consequently financial literacy among older people has largely been confined to debates around income and resources in or approaching retirement. This suggests the value of seeing personalization as part of the political economy of old age (Mann, 2006). This influential gerontological theory continues to offer helpful insights into the macrolevel of personalization. The development of options for social care presents challenges for older people who may face them at times of increasing frailty. It will be important to consider ways in which older people may develop understanding, skills and confidence in consumer roles prior to illness or disability or may prefer less individualistic transactions.

Conclusion

The discourse of choice and control tends to veer on the hypothetical and abstract; far less on the microlevel financial transactions, the management of the money, and day-to-day decisions. Aspects such as contract law, employment obligations, and training all feature when describing the administration of personal budgets, but less often articulated are the interactions of managing a disability, coping with changes in income, relationship building and sustaining, or nonfinancial transactions. There is a danger that, in stressing the work and microlevel financial aspects of personal budgets, the wider potential for personalizing care and support may evaporate. However, insights from theories of the political economy of old age suggest the value of understanding shifts in and connections between financial and individual responsibilities. 'Training' to be an older person in need of care and support may seem overly burdensome and characteristic of a highly atomized society where social support and interdependence are no longer marks of citizenship. Personal budgets and their equivalents are seen as a cornerstone to achieving the policy aim of enabling older people and their carers to take control and exercise choice over their care and support. To achieve these benefits, a variety of approaches to supporting older people in the process of planning and management seem necessary (see Newbronner et al., 2011) The question remains: will sufficient resources be available for

adequate personal budgets and to employ professionals who can sustain the flexible and creative approaches needed to support different groups in achieving their desired outcomes? Netten et al. (2012) concluded that a policy with potential for considerable improvements in people's lives is taking place in a context that undermines its capacity for success.

Self-Efficacy

August Flammer, University of Berne, Bolligen, Switzerland

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Purposive actions as well as positive self-esteem presuppose corresponding self-efficacy beliefs, that is, beliefs that one has the capacity to efficiently use means that lead to desired states. On the opposite, people who perceive themselves as helpless are unhappy and are not motivated for actions. The concept of self-efficacy, as it is mostly in use today, emerged between the forties and the eighties (Heider, Rotter, Seligman, Weiner, Bandura, E. Skinner).

This article treats the main concepts related to self-efficacy, their theoretical and historical roots, their functions and practical uses, as well as developmental and educational/therapeutic aspects. The individual development of self-efficacy beliefs has its roots in early contingency experiences (starting in the first weeks after birth), in the use of degrees of freedom and in the experience of success and failure depending on appropriate causal attributions. These basic experiences also hint at the most effective educational and psychotherapeutic approaches. In front of an actual task, adults trust in their necessary abilities mainly on the basis of their memory of former experiences of comparable success (or failure, respectively). In comparison, adolescents and children are more optimistic than adults and give themselves more often a chance, even if the task is totally new and unknown to them.

Concepts

Everything that happens is caused to happen (Aristotle). Making changes means being a cause or providing a cause that produces a change. True causal changes are difficult to identify, because we are mostly confronted with causal chains and because most changes are due to a multitude of causes or conditions. A car accident may be considered as due to exceed speed, but it may also depend on street conditions, lighting, car conditions, car handling, weather, and so on. What is *the* cause? In everyday life people often choose the most salient condition or an unusual condition to be identified as cause. Here, we prefer the term condition(s). An effect is contingent upon a condition or a set of conditions if it always occurs if the condition or the set of conditions is met. Such conditions may be sufficient but not always necessary for producing the effect.

In this article we are interested in human actions as necessary conditions of change. The success of actions, too, depends on conditions. Considering person-related conditions of effective actions, we differentiate aspects like knowledge, initiative, perseverance, intelligence, experience, physical force, help from others, and more. Thus, instead of saying that an actor is able to produce a certain effect, we can say more elaborately that an actor is endowed with certain means or conditions that enable him or her to attain certain goals. Figure 1 represents a simple two-set causal chain: An actor who activates certain conditions that produce a certain effect.

We say that individuals (as well as groups) are in control of specific goals if they are able to produce the corresponding changes (horizontal line of Figure 1). More elaborately, people are in control of a specific goal if they are aware of the necessary contingencies and if they are competent enough to make these contingencies work (both diagonal lines in Figure 1). Instead of control, Bandura (1977) introduced the word efficacy, more specifically: self-efficacy. We use control and self-efficacy interchangeably.

Controlling means putting control into action. This is not equivalent to having control or being in control: People are in control of certain states or changes of affairs, if they can put control into action, even if they do not. For example, somebody has control over buying a new bicycle (having enough money, knowing where and how to execute a purchase), even if he or she does not buy it – even if he or she never in life buys a bicycle.

People may indeed be able to control certain events without knowing it; they will then eventually miss possible chances to activate such control. On the other hand, people may believe that they have control over a certain range of affairs, but in fact do not. That may make them feel good as long as there is no need to put this control into work, but they will be frustrated if they try to put their believed control into action and possibly regret not having prepared themselves for real self-efficacy.

Figure 1 Means-ends relations and agency as components of control. Adapted from Skinner, E.A., Chapman, M., Baltes, P.B., 1988. Control, means-ends, and agency beliefs: a new conceptualization and its measurement during childhood. Journal of Personality and Social Psychology 54, 117–133; Flammer, A., 1990. Erfahrung der eigenen Wirksamkeit [Experiencing One's Own Efficacy]. Huber, Bern, Switzerland.

Obviously, it is important that people not only have control, but that they also know that they have control; they need corresponding control beliefs. Not being in control of an important situation is equivalent to being helpless in this respect (Seligman, 1975). The same is true, if a person only believes that he or she be not in control of an important situation. It has been proved that the psychological effects of helplessness (HL) are different depending on whether the helpless person believes being helpless for ever (chronic HL), whether being helpless is unique (personal vs universal HL), and whether HL is related to a specific domain or to most domains of life (specific vs global HL). Erroneously believing in personal and chronic HL in important domains is a tragic buffer against changes to the better. On the other side, chronic and universal HL over weather conditions does not hamper the person's self-value, because nobody can control the weather. But personal HL over important events that other people are in control of is difficult to accept (cf severe bodily handicaps). In sum, the psychological consequences of believing not to be in control over important domains are fourfold. Severely helpless people are (1) deeply sad about not having control, (2) demotivated to take initiatives or to invest effort and perseverance, (3) cognitively blind for any alternative or better view of the state of the world, and (4) devaluate themselves.

Obviously, at least in subjectively important domains, we prefer self-efficacy to helplessness. As long as we are not completely demotivated we either strive for self-efficacy in important domains (by fighting, learning, or training) or search for compensation. A common type of compensation consists of seeking help or delegating personal control (indirect control or proxy control), for example, to pay a gardener for caring one's garden or to put a doctor in charge with one's health, or to pray to God for a favor in a seemingly hopeless situation.

Another way of compensating noncontrol is to use secondary control (Rothbaum et al., 1982). While control as discussed above (i.e., primary control) consists of making the world fit with one's goals and aspirations, secondary control accommodates personal aspirations or personal interpretations of the actual state to make them fit with the world. As an example, a person who was not admitted to physics studies of his or her University may later 'find out' that working day and night in physics laboratories makes one miss the beauties of the rest of the world.

Very often people act in groups or teams. Take a soccer team as an example. Victory depends on the actions of each individual (even on the actions of the opposed team's individuals, etc.). However, each individual's action is really effective only if it is coordinated with the others' actions. Self-efficacy belief therefore also depends on the trust in others' capabilities and their coordination. The same is true for each team mate: Each of them has to believe in himself or herself and even in the efficacy as well in the self-efficacy beliefs of each other. Thus successful teams have to collectively care for their collective self-efficacy (Bandura, 2000; Stajkovic et al., 2009).

History of the Concept of Self-Efficacy

In the 1950s, Rotter (1954) proposed the concept 'locus of control,' meaning the place where control of desired reinforcement for behavior is exerted. Internal control means that the person gains reinforcement by his or her own sovereign actions. External control means that agents outside the person determine whether reinforcement occurs, possibly powerful others, situational conditions, chance, or luck. Rotter and his associates have developed valid measuring instruments that have been used in thousands (!) of studies demonstrating that internal locus of control is positively correlated with almost all desirable attributes of humans.

Fritz Heider (1944), an Austrian researcher of social perception, studied the subjective interpretations of (i.e., 'causal attributions' for) observed actions and did so by using the concepts of internality and externality. The true origin of an observed action is attributed either to the person (internal) or to person-independent conditions (external). In the first case, a person is responsible for the action outcome, in the second case he or she is not. Heider's work has triggered a large research tradition on causal attributions, whereby cause is understood in a very large sense (see above). Results of this research were of use for successful differentiations of subjective interpretations concerning experiences of control and of helplessness (*see* Attributional Processes: Psychological). Consequently, attribution theory remains an important element of self-efficacy theory.

Modern self-efficacy theory goes beyond Rotter's theory insofar as it is more differentiated (e.g., contingency vs competence, primary vs secondary, personal vs universal, chronic vs transient, specific vs global), distinctively referred to specific domains of actions (e.g., health, school), and elaborated to also include more personality aspects like motivation and development.

Self-Efficacy as an Important Element of a Happy and Successful Person

Individuals with high self-efficacy beliefs also report strong feelings of well-being and high self-esteem in general. Self-efficacy beliefs influence motivation, perseverance, social attitude, health, recovering from illness, learning efficiency, and so on (Bandura, 1997; Flammer, 1990; Maddux, 2009). It feels good to be good. Such persons are willing to take initiatives in related domains, to apply effort if needed, and persevere in efforts as long as they believe in their efficacy. Clearly, such initiatives may sometimes be unsuccessful, but more often they provide learning chances and lead to new experiences opening up new perspectives of the world and of the personal development (snowball effect). Optimistic persons with a high sense of self-efficacy do not give up easily and are able to overcome difficulties that others do not.

It is well documented that very low self-efficacy beliefs can be a basis of depression, especially if it is coupled with the conviction that not only the concerned person can change the situation but that nobody else is able to help (chronic and universal helplessness, i.e., hopelessness).

As to gender differences, in average – but only in average – females are less confident of their self-efficacy than males; the other side of the coin is that males are more often overconfident than females. It is a common finding that girls often outperform boys in school but still hold lower self-efficacy beliefs than

boys. As a consequence, girls less often show self-enhancing attribute patterns than boys, that is, have a stronger tendency to attribute failure to insufficient abilities and success to external factors. This is especially true in achievement domains that were long hold as masculine. Possibly – hopefully – new socialization patterns (new self-experience and more veridical and accurate feedback) will make these gender differences disappear (e.g., Lloyd et al., 2005).

In highly self-efficient individuals, potentially stressful situations produce less subjective stress, because such individuals are confident in having the competencies for finding ways to overcome hurdles. However, while self-efficacy beliefs act as buffers against stress, they can also – indirectly – produce stress insofar as they can induce overly ambitious individuals to assume more responsibility than they are able to cope with. Either the goals are in fact beyond their competence or the sheer quantity of chosen goals to be attained exceed the persons capacity.

Self-efficacy beliefs have also been reported to exert a positive influence on recovery from surgery or illness and on healthy lifestyles. If you believe that your health fully depends on fate or on medical art and effort, you do not personally think and care about what in your life-style could be changed to become or to stay healthy. However, if you think that personal health is at least partly a personal performance, you try to do your best.

High self-efficacy beliefs not only often root in success experience, they also produce success (Schunk and Pajares, 2009; Zimmerman and Schunk, 2009). In the school domain the circular effects between belief, effect, and belief again are easily apparent. Those who believe in themselves invest more effort and as a result of it experience more success, which in turn boosts the belief in further success. Likewise, students who are convinced of their incompetency refrain from effort (or simply feign effort) and consequently have little success, which in turn proves that they are right in not believing in their self-efficacy (circulus vitiosus). Not surprisingly, these good and bad circles have also been studied systematically in the area of sports, especially in high-performance sports (Feltz et al., 2008). Athletes as well as coaches are well advised taking lessons from these insights.

Interestingly, it has been demonstrated repeatedly and in several cultures that in most domains healthy and happy individuals tend to slightly overestimate themselves. If people are asked to compare themselves with the general population of their kind and indicate whether they are about the same (0) or healthier or more good looking or brighter (1 or even 2) or whether they feel they are below average (−1 or even −2), the average of the answers is clearly above 0. This has also been found with respect to self-efficacy: In average, people feel more self-efficient than average. Furthermore it has been found that realistic estimation of self-efficacy is rather typical for persons vulnerable to depressed mood, and clear underestimation increases the chance for a clinical (reactive) depression. Slightly overestimating one's own self-efficiency is healthy and boosting development toward the better, which allows for even higher expectations (snowball effect). However, there is a limit somewhere: Major overestimation can result in painful and harmful clashes with the reality and finally severely undermine realistic judgments.

The Development of Self-Efficacy Beliefs

Even the newborn baby has efficacy, but not really efficacy beliefs. The basic structure of the self-efficacy beliefs develops within the first 3 or 4 years. According to Flammer's (1995, 2009) analysis, the infant's development toward the basic understanding of self-efficacy proceeds through a developmental sequence consisting of the acquisition of (1) the basic event schema, (2) the elementary causal schema, (3) the understanding of personally producing effects, (4) the understanding of success versus failure in aiming at nontrivial goals, and (5) the discovery of being not only the origin of one certain change but also capable of producing such changes more generally.

The basic event schema consists in being aware that certain classes of events happen. These events are mostly very complex like: adequately sucking, smelling, tasting, and drinking milk, or moving the legs, perceiving rhythmical movements in the body, and seeing a suspended toy swinging above the head. The fact that such movements are becoming more 'rounded' and adapted, that is, that learning takes places, indicates that the baby experiences what happens. By the way, this is what Karl Bühler almost 100 years ago has defined as 'Funktionslust' and what Piaget not much later has theoretically interpreted as primary circular reaction.

The elementary causal schema is reached when babies start to recognize that two or more events hang together in the sense that one follows the other. The pleasure provided by tickling games or by seeing and then hearing objects banging on a hard surface shows that the baby is expecting effects, that is, contingency.

Soon after the second stage, the baby starts to experience herself as producing effects. She realizes that certain effects are produced by others that and some effects are their own. If they like it, then they may repeat the same action again and again; and later on the sheer visibility of a pertinent object or situation can trigger the resumption of the causal action. This is what Piaget called secondary circular reaction. Very soon, these are followed by tertiary circular reactions: Infants not only try to reach goals but also test possible means or causes through varying their actions and finding out what different changes they produce. Clearly, not all actions are successful, but this does not matter much to the baby so far, she simply tries again. Success and failure, however, have much more impact on the next stage.

Infants in their third year or so are not only happy in producing effects, but show pride in successfully reaching nontrivial goals like building a high tower with wooden game blocks. A high tower done by her mother may be admired, but a high tower done by one-self magnifies the ego. Reversely, failure despite hardly trying to reach an important and publicly visible goal results in shame: Such infants may corporally sink down in their chair and lower the eyes. Apparently, self-efficacy is more than reaching effects, it means something to the self-value.

Finally, the belief of one's self-efficacy generalizes. It is not just this or that effect one has successfully reached or not, but it is one's own personality that is effective, successful – or not with all the further consequences alluded to above.

Obviously, this stagewise development proceeds in domains that are accessible by the infant so far. A major opening of new domains comes with school entrance. As to

the domain of school success, within the second half of the first decade of life, the child learns more and more differentiations of means toward the same ends. Thus, he or she gradually abandons a global concept of simply being or not being able and singles out – probably in this sequence – (1) the factor effort (more effort is needed to solve tasks, which is a typical lesson to be learned early in school), (2) the factors individual ability and task difficulty (higher difficulty requiring more ability; higher ability allows mastering more difficult tasks), and finally (3) the understanding of the compensatory relation between effort and ability (it is possible to reach the same goals by being less capable but more hard working; not yet mastering certain tasks calls for learning and acquiring higher ability).

In adolescence and in early adulthood more lessons have to be learned; more and more domains become accessible to personal control due to increased cognitive, physical, or economic strength and social power. This is exciting, indeed. However, individuals have to permanently select from the choices that are offered to them (Flammer, 2009). Trying to control everything results in overburdening. One thing is to deselect control domains because they compete with higher priority control domains; another thing is to be forced to renounce control because no accessible contingencies seem to exist. As long as there are enough attractive alternatives available, renouncing is not very painful, but it can severely hurt handicapped individuals and old people when they lose control of important domains.

Old people are well advised not to resign too early but eventually to search for compensations. Such compensations consist of artifacts of all kinds (from memory aids to hearing aids), but they also include the above-mentioned compensations like indirect control (social resources) and secondary control. Indeed, it seems that the extent and the importance of secondary control increase with the lifetime (Heckhausen and Schulz, 1995). In old age, more and more control is taken over by care persons. A few homes for old people even take over so much control over their patients (this Latin expression means endure, bear, tolerate) that M. Baltes and Silverberg (1994) have even suggested that people in such homes adjust better if they give up personal control at all. Alluding to the concept of learned helplessness, they called such behavior learned dependency. Learned dependency helps to avoid certain social conflicts; the only remaining personal control then is the control over giving in.

The Microgenesis of Self-Efficacy Beliefs

If a person starts an action, he or she is convinced or at least hopes to be able to successfully perform. Remembering earlier experiences is probably the most reliable basis for the actual belief. However, if the person is confronted with a concrete difficult and possibly difficult task, how does he or she come to believe in being able or not being able to solve it? – This is the microgenetic question (as opposed to ontogenesis (lifelong development of the individual), the German Gestaltists called the actual or short-term building up or emergence of an idea or of a perception as 'Aktualgenese,' which we translate as microgenesis).

Even if people have had appropriate past experiences, relevant knowledge has to be activated, retrieved, or reconstructed from memory. And even then the result may be an underestimation or an overestimation of one's actual control. As an example, clinically depressive persons tend to remember more negative experiences than positive ones – even if compared with the proportion of really experienced success and failures – thus negatively biasing their expectations for further actions even more.

In a series of studies, the author has interviewed adolescent and adult subjects about several possible tasks and challenges. After the response (yes or no) he eventually asked them in a seemingly casual way 'Why?'. The results indicated that individuals most often refer to dispositional attributes, that is, ready-made generalized beliefs (i.e., 'because I am strong'). Second in frequency were references to personally experienced episodes (surprisingly, there were almost no references to models, i.e., to other people who did the same, successfully or not). However, when later asked about their confidence in believing to be able or not to be able, the subjects indicated more confidence in those control beliefs for which they had referred to concrete experiences than in those based on dispositional attributes. This in spite of the fact that they referred to dispositions more often than to experienced episodes. Also, the latencies before the yes/no answers were shorter, when the subsequent reference answer was episodical rather than dispositional. Taken together with the finding that in the oral format the episodic answers were more frequent than in the written format, these results indicate that people prefer the episodic foundation of their self-efficacy beliefs, but often do not have ready access to relevant remembered episodes. That episodical reference is taken as trustworthier is also shown by the result that people are also more confident in other people's assertion of competence if they refer to repeated former experiences than if they refer either to their general abilities or to one unique experience.

There is also an interesting interaction between ontogenesis and microgenesis. The author and his coworkers have also confronted elementary school children with the same frame of questioning. Unlike adults, children often simply asserted how they would do (i.e., being totally confident that they are able). If questioned again, they often answered – very optimistically – that they would try very, very hard. In one respect, this corresponds with earlier data from adolescents: Compared with adults, adolescents referred more to dispositions, when they positively believed in their self-efficacy, but less when they believed in their nonefficacy. It seems that adolescents – like children – are still very optimistic as to their self-efficacy unless they have experienced specific failures. They are probably not only right but also serve their developmental chances.

Another source of one's own capacity estimates (as well as overestimate and underestimate) is the actual mood state. Positive mood raises control self-efficacy belief, negative mood lowers it, which obviously has the potential of vicious and eventually virtuous circles. Failure produces disappointment and bad mood; bad mood makes failure more salient, so that the individual either avoids challenges or chooses unsolvable tasks; this produces failures and the repeated 'perception' of one's own deficiencies. The reverse is true as well: Positive

mood induces initiative, effort, and perseverance, which may lead to success, and success raises the mood – and adds another positive event to be encoded in memory.

Educational and Therapeutic Aspects

Parents and educators can influence not only the actual self-efficacy beliefs but also life-long generalized trust in one's competence. Contingent behavior by the caregivers is crucial already within the first weeks of life. Caregiver's behavior should be predictable, that is, contingent upon the baby's actual behavior – even more upon the baby's perceptions, feelings, and desires. Contingent behavior fosters not only children's happiness, but also their curiosity and their willingness to learn. This requires high sensitivity toward the child.

Fortunately, parental empathy – a basic condition for contingent behavior – is a natural gift in the majority of attentive parents. But contingent and reinforcing behavior is not always easy. External stress, health, and too frequent changes in caregiving teams make the educational task difficult. In addition, if the baby shows unorganized behavior (so-called difficult babies), the caregiver's task is not only difficult but often less rewarding.

Infants and children need freedom for experimentation. Caregivers are to give the necessary freedom, but to prevent from dangerous experimentation. With the infant getting older, the caregiver has to help her to understand success and failure adequately (causal attribution): An action might be too difficult at a certain age or the young child may be encouraged to learn or simply to try again and invest more effort (Schneewind, 1995).

Clearly, self-efficacy beliefs need to be carefully maintained or even boosted in adolescents and in adults as well. Giving a good job interview, delivering a public speech, or successfully participating in a sports competition can be much helped by a sound belief in one-self. The same is true for elite sports and the systematic and enduring training that needs perseverance and optimism even in case of setbacks. Feltz et al. (2008) are a perfect example of how to train systematically self-efficacy beliefs of athletes, teams, and even coaches. Evidently, not only individuals need to believe in their own efficacy, but teams as well.

Psychotherapy with persons whose self-efficacy beliefs are severely undermined is difficult. Helpless people not only tend to interpret failures to their disadvantage, they also often play down their contribution to eventual success. They therefore lack or even avoid initiatives. Persons who have lost self-confidence immunize themselves against being hurt by not trying anymore, by fatalistical attributions, and even by recalling their biography in a way that is consistent with and justifies their dysfunctional beliefs. Teaching and trying to convince them that they are really capable despite their belief not to be does not help much. Helping them to recall from memory prior success experiences instead of being impressed by failures only is (a bit) more efficient. More efficient are new and successful experiences.

Conclusion

Within the past decades, theory and research have established self-efficacy beliefs as important elements in the understanding of human action and human well-being in a very large sense. The theory is rather well established, empirically founded, and linked to a multitude of other scientific domains. Further steps may include more differentiation between life domains, between cultures and – if possible – between historical times. Given the importance of life-long high self-efficacy beliefs, the developmental conditions surely merit more attention by researchers.

Abstract

This article provides an overview of the literature on self-efficacy in producing health-related behavior. It shows that the evidence that self-efficacy predicts many such behaviors is strong, but the evidence of causation is not entirely compelling. It evaluates the evidence on how best to increase self-efficacy, and on the mechanisms by which self-efficacy influences behavior. Throughout, evidence is used to evaluate propositions derived from relevant theory, i.e., social cognitive theory.

Introduction

Definition

Self-efficacy has been defined as "beliefs in one's capabilities to organize and execute the courses of action required to produce given attainments" (Bandura, 1997: p. 3). Thus, self-efficacy is an individual's perceptions of control over his or her ability to successfully complete a behavior or behaviors, in order to bring achieve his or her goals.

Historical Development

Self-efficacy, as a concept, was emerged from social learning theory, which has several variants (e.g., Rotter, 1954; Bandura, 1977a). Social learning theories were proposed to contrast with previous learning theory approaches to understand behavior, which emphasized the key role of conditioning through reinforcement of a person's behavior. By contrast, the key insight these various social learning theories shared is that, as the name suggests, people often learn by observing others, i.e., by learning within a social context. An influential series of studies for social learning theory were Bandura's 'Bobo doll' studies, where nursery school children saw adults hitting inflatable dolls with bats (Bandura et al., 1963). The main influence on whether the children copied this behavior was the extent of reward for the others, indicating that the children were learning by observation of their social context, not by being personally reinforced, the form of learning emphasized by learning theory.

This work had demonstrated that outcome expectancies were important in determining behavior, i.e., beliefs that a behavior would lead to a particular outcome. Social learning theory subsequently incorporated discussion of beliefs about capability to perform the behavior, i.e., self-efficacy, which were also shown to be important (1977b). The precise nature of the factors involved, how they were brought about, and how they influenced behavior were elaborated in the subsequent social cognitive theory (Bandura, 1986).

Role of Self-Efficacy in Social Cognitive Theory

According to social cognitive theory (Bandura, 1986), the behavior that individuals choose to carry out is chosen as it helps them achieve their goals (see **Figure 1**). Self-efficacy is hypothesized to be an important determinant of these behaviors, in combination with outcome expectancies, i.e., beliefs about the likely outcomes of the behavior. For example, if a person has a goal of weight loss, he or she may consider that not eating candy would help them achieve that, which is an outcome expectancy. In this example, whether a person attempts to reduce eating candy would depend upon whether they believe they can successfully do so, i.e., their self-efficacy with regard to this behavior. It is important to note that, high self-efficacy for performing a behavior on its own is unlikely to produce a behavior where a person has a low outcome expectancy, i.e., they do not believe that performing that behavior will bring about a particular goal. Equally, if a behavior leads to a goal that is not valued by that person, e.g., they do not wish to lose weight, levels of self-efficacy will be irrelevant.

The importance of self-efficacy, according to social cognitive theory, lies in the insight that a person only believing that performing a behavior, e.g., not eating candy, will lead to a desired outcome, e.g., losing weight, is not sufficient to produce behavior. A person must also have a sufficient level of self-efficacy, i.e., must believe that he or she has the capability to not eat candy for the behavior to be brought about. There is often much variation in levels of self-efficacy for many common health-related behaviors, given that they are difficult to carry out, e.g., stopping smoking, avoiding eating tempting sugary or fatty foods, or increasing the levels of physical activity.

Role of Self-Efficacy in Multiple Theories of Behavior

Self-efficacy has subsequently been recognized as one of the most important constructs within psychology, with a wealth of applications in health, educational, and work settings, among others (Bandura, 1997). Within the health sphere, it is now a core construct, being adopted by many leading theories of behavior, including the transtheoretical model (Prochaska and Velicer, 1997), protection motivation theory (Rogers, 1983), and the theory of planned behavior (Ajzen, 1988) in the form of the closely related construct of perceived behavioral control.

Figure 1 Paths of influence through which perceived self-efficacy and other key social cognitive factors regulate motivation and performance accomplishments.

Role in Determining Health-Related Behavior

Evidence Required to Establish Causation by Self-Efficacy

It is important to be precise when describing the role of self-efficacy in bringing about behavior. A construct such as self-efficacy can be a correlator or predictor of subsequent behavior without necessarily being causally involved in producing that behavior: they could both be causally produced by a third construct, such as social support. There is stronger evidence for causation when self-efficacy mediates change of behavior following an experimental intervention; although, this is not sufficient to demonstrate causation (see French, 2013). It is widely agreed that one of the most effective methods of increasing self-efficacy is for a person to successfully perform that behavior (Bandura, 1997; see also below). Given that, an intervention may change behavior via another mechanism, e.g., by forming effective plans, which is likely to increase self-efficacy in turn. In this scenario, mediation analysis may suggest that self-efficacy is the mechanism responsible for changing behavior when it is not.

Evidence for Self-Efficacy as a Determinant of Health-Related Behavior

There is overwhelming evidence that self-efficacy is a reliable predictor of many health-related behaviors, including healthy eating, screening, safer sexual behavior, and smoking, and also of changes in many health-related behaviors (Luszczynska and Schwarzer, 2005). There is also good reason to believe that it can play a causal role in behavior change, although the evidence for this is not entirely compelling (French, 2013).

As an example of this, there is a wealth of evidence that self-efficacy is a consistent correlate of physical activity in adults (Bauman et al., 2012). However, self-efficacy had mediated the effects of few interventions to increase physical activity (Rhodes and Pfaeffli, 2010). Two good reasons for this pattern of results are many interventions fail to change self-efficacy in the first place, which makes them essential uninformative about the role of self-efficacy in changing behavior and many interventions do not increase physical activity; there are no effects to mediate (French, 2013). However, there are some studies, which provide convincing evidence of mediation, and grounds for belief that self-efficacy played a causal role. For example, one intervention study specifically targeting increasing self-efficacy as a method to increase walking behavior, and produced large increases in objectively assessed walking (Darker et al., 2010). Notably for the present purposes, the intervention was delivered in a single session, and a large change in self-efficacy was observed over the course of this session. This change in self-efficacy mediated the effects of the intervention on walking behavior subsequent to this intervention session. As well as satisfying the statistical tests of mediation, the timings of intervention and measurement in this study make explanations for this mediation other than self-efficacy having a causal role in changing behavior, unlikely.

It is worth noting that there is stronger evidence that self-efficacy is a determinant of many physical activity interventions for older adults (van Stralen et al., 2009), and solid evidence that self-efficacy is a mediator of many interventions with children and adolescents (Lubans et al., 2008). In general however, there is a need for further well-designed intervention studies to further test the hypothesis that changes in health-related behavior can be brought about by increasing self-efficacy.

Reciprocal Determinism

Much research on social cognitive theory has been concerned with the role of individual factors such as self-efficacy in producing behavior. Despite this, the theory proposes that there are three major classes of determinants (internal personal factors, behavior, and the external environment), which all influence each other (Bandura, 1986). Thus, if a person changes his or her behavior, due to having high levels of self-efficacy, it can in turn influence his or her environment, e.g., a person quitting smoking makes in more likely that others close to them will also quit (Christiakis and Fowler, 2008), thereby shaping their environment to make it more supportive of not smoking.

Equally, the theory emphasizes the crucial role of the environment in shaping individuals and their behavior. Much behavior, including health-related behavior, is socially

patterned (Steptoe et al., 2010), e.g., there is a clear decline in smoking status associated with higher incomes. There are likely to be many reasons for these patterns, but by highlighting the influence of the environment on behavior, the theory highlights the limitations of interventions that try to change an individual's unhealthy behavior without also trying to alter the environment, which makes that unhealthy behavior more likely. It also indicates that low self-efficacy may often be a consequence of adverse environments, e.g., a person who lives in a neighborhood where shops do not sell fresh fruit and vegetables faces more barriers for eating a healthy diet, and would have to expend more effort in doing so than a person living in a more supportive environment.

What Is the Best Method for Increasing Self-Efficacy?

Bandura's Four Sources of Information about Self-Efficacy

Bandura (1977b) proposed four main sources that people draw upon when evaluating their levels of self-efficacy: mastery information, vicarious experience, persuasion, and affective/physiological feedback.

Mastery experience is generally held to be the strongest and most convincing source of information (Bandura, 1997): to the extent that a person has successfully performed a behavior in the past, such as exercising regularly, they will tend to be confident that they can do so in the future. Similarly, if a person has repeatedly failed at performing a behavior in the past, e.g., quitting smoking, then his or her self-efficacy for future quitting will tend to be low. Vicarious experience refers to seeing another person performing the behavior, as with the example cited earlier of hitting a bobo doll. Its influence on self-efficacy for that behavior will be strongest when the other person is seen as being similar in terms of salient features. For example, seeing a famous sportsman modeling engagement with exercise is unlikely to lead to much increase in self-efficacy for exercise in a fairly sedentary person in middle age. In contrast, seeing a person successfully engaging with exercise is more likely to increase self-efficacy, where that person is perceived as being similar in terms of levels of activity, age, and gender especially where other personally salient barriers are similar, e.g., a chronic condition is shared. Persuasion is generally held to be the least convincing source of information (Bandura, 1997), consisting of messages designed to convince that the behavior is easy or under a person's control or that the messages have the capability to perform the behavior. Finally, affective/physiological feedback refers to the influence of internal sensory or emotional cues on evaluations of self-efficacy. For example, if a person trying to quit smoking is feeling depressed or lethargic, it may make him or her feel that the demands of quitting are unmanageable, and hence beyond his or her control. Similarly, feeling tired and achy following an intense burst of exercise in a sedentary person may convince that person that he or she does not have the capability to exercise on a regular basis.

It is important to note that for all these sources of information about self-efficacy, the key factor is a person's interpretation of that information, not the information per se that is important in forming that person's evaluation of self-efficacy (Bandura, 1977b).

Which Behavior Change Techniques Lead to Increases in Self-Efficacy?

Subsequent to Bandura's work, other sources of self-efficacy have been proposed, notably imagery (Maddux, 2002). In particular, there is some evidence that encouraging people to imagine successful sporting performance can enhance self-efficacy, and possibly performance (e.g., Callow and Waters, 2005).

To test Bandura's theorizing, reviews have assessed whether there are differences in the extent to which interventions change self-efficacy, according to whether behavior-change techniques (BCTs) are included or not. One review identified interventions aiming to increase lifestyle or recreational physical activity (Ashford et al., 2010), and coded the contents based on a coding scheme derived from the four sources proposed by Bandura (1977b). This review found that techniques involving mastery experience or persuasion were the most commonly used, being used by respectively, 33 and 34 interventions out of a total of 37 interventions included in the review. Interventions using persuasion produced less of an increase in self-efficacy than interventions that did not include persuasion. In contrast, those interventions which involved vicarious experience of success by others were less common, being used in only nine interventions, but were associated with larger increases in self-efficacy when compared with those that did not involve vicarious experience.

More recent reviews have used standardized taxonomies of BCTs, which are general in scope, and not linked to self-efficacy specifically. These reviews have identified those techniques, such as action planning (i.e., getting a person to specify where, when, and how to perform the behavior), that were associated with larger increases in self-efficacy for physical activity when included in interventions with nonclinical populations (Williams and French, 2011). Thus, these reviews allow the identification of apparently effective BCTs that are derived from theories other than social cognitive theory. Further, these reviews have also examined, which BCTs are associated with increases in physical activity. A notable finding is that there is a high degree of association ($r = 0.7$) between change in self-efficacy for physical activity and physical activity behavior in nonclinical populations, as well as a high degree of association ($r = 0.7$) across change in physical activity and self-efficacy when examined by BCT (Williams and French, 2011). Thus, within this population, those BCTs that were associated with larger increases in self-efficacy were also associated with larger increases in physical activity; conversely, those BCTs that were not associated with changes in self-efficacy also tended not to be associated with changes in physical activity. It should, however, be noted that a review of studies with obese participants did not find such an association, suggesting that self-efficacy for physical activity may not be as important as a determinant of physical activity in such populations (Olander et al., 2013).

How Does Self-Efficacy Determine Behavior?

According to Bandura (1977b), self-efficacy is a determinant of behavior, as it affects attempts at both initiating attempts at changing a behavior, and persistence of attempts at behavior

change. In terms of initiation, people who are low in self-efficacy with regard to a particular behavior will be disinclined to attempt that behavior. For instance, those who believe they cannot quit smoking will be reluctant to make a quit attempt. Further, as low feelings of self-efficacy for important goals result in lowered affect (cf Carver and Scheier, 1982), people tend to avoid even thinking about attempting that behavior. Thus, they will not tend to seek out information about changing this behavior, even when such information could potentially be of benefit, such as the helpful role of pharmacological agents that reduce cravings for nicotine in dramatically increasing the success rates for quit attempts. This motivated lack of information seeking is a contributor to 'defensive processing' in the face of information about the harms of a behavior: where a person thinks that he or she cannot change a behavior, tend to ignore or otherwise derogate messages about the harms of that behavior (Croyle et al., 1997).

In addition to being more likely to initiate an attempt at changing behavior, those high in self-efficacy are more likely to persist even in the presence of obstacles and aversive experiences. Hence, a smoker who believes that he or she can successfully quit is likely to make more attempts, as he or she will attribute the failure of a quit attempt to an unstable and potentially controllable factor, e.g., drinking too much at a party, rather than making a stable dispositional attribution: they are the kind of person who cannot stop smoking. Similarly, they may be more likely to attribute bodily signs such as nicotine craving as indicating that they are successfully removing the effects of smoking from their bodies, rather than as a sign that their body needs nicotine.

More recently, theorists have proposed that people may have self-efficacy relating to specific actions that constitute an overall behavior. Specifically, in the area of addictions, Marlatt et al. (1995) proposed five distinct types of self-efficacy: resistance, harm reduction, action, coping, and recovery self-efficacies, relating to addictive substances, such as tobacco and alcohol. Each of them relate to feelings of control, overrespectively, avoidance of addictive substances, minimizing risk once having tried the substance, quitting/abstaining from taking the substance, coping with barriers that arise from abstaining, and dealing with lapses in abstinence. More recently, refinements to this scheme have been proposed by others, with relevance to health behaviors in general (e.g., Luszczynska and Schwarzer, 2003). They proposed instead pre-action self-efficacy, relating to self-efficacy relating to formation of intentions to change, and two postintentional forms of self-efficacy: maintenance self-efficacy, which is similar to Marlatt et al.'s (1995) coping self-efficacy, and recovery self-efficacy, in line with Marlatt et al.'s (1995) definition, although it has been called relapse self-efficacy in later work. These latter distinctions are based upon the idea of there being distinct psychological processes involved in forming intentions and changing and maintaining behavior, in line with the Health Action Process Approach (HAPA; Schwarzer, 1992). The HAPA builds upon earlier theorizing within social cognitive theory, but emphasizes the role of stages of behavior change, and provides greater elaboration of the processes involved following formation of intentions. There is empirical evidence to support the utility of the distinctions between these different classes of self-efficacy in the maintenance of behavior (e.g., Kassavou et al., 2014).

Conceptual Issues

Specificity versus Generality of Self-Efficacy

An ongoing issue regarding the conceptualization of self-efficacy concerns the most appropriate level of specificity for the construct, and at which it should be measured and its effects assessed (Bandura, 1997). Bandura's work generally conceptualizes self-efficacy as being specific, in terms of either a behavior, or components of that behavior (1997). The logic of this is that a person may well be very confident that he or she can exercise regularly but not prevent him or her from eating sweet or fatty foods; in contrast, another person may feel in the control of their ability to avoid eating unhealthily but not feel in the control of increasing their levels of physical activity. These two individuals may therefore attempt to achieve the same goal (maintaining a healthy weight) by performing different behaviors. Following similar reasoning, as a function of self-efficacy, is to help people overcome barriers to them achieving their goals, it makes sense to examine self-efficacy for different behaviors separately, as the barriers are likely to be different.

Despite this, some theorists have proposed examining self-efficacy at a broader level, e.g., self-efficacy for achieving weight loss, which is clearly a goal rather than a behavior. At its most broad, the construct of general self-efficacy has been proposed (Schwarzer and Jerusalem, 1995), which is an overall stable sense of competence to overcome some barriers.

Distinguishing Self-Efficacy from Other Control Constructs

The issue of generality of self-efficacy highlights that there is a multitude of other constructs relating to control: Skinner (1996) identified over 100 constructs relating to control that were in use. Given this, it is important to be clear on how self-efficacy differs from other commonly used constructs.

One key distinction is between control over means of achieving ends, i.e., control over behavior, and control over the ends themselves, i.e., control over ends. Skinner (1996) argues that Bandura unambiguously defined self-efficacy in terms of control over behavior in his earlier writing (e.g., Bandura, 1977), but shifted over time to control over ends (e.g., Bandura, 1997). This has two implications. First, that self-efficacy, as latterly defined, becomes akin to Rotter's (1954) concept of locus of control, which relates to how in-control people feel of events that affect their lives. Secondly, and crucially, it has been argued that most measures of self-efficacy conform to latter definitions regarding control over ends (Williams, 2010). That is, measures of self-efficacy assess not only self-efficacy as intended, but also outcome expectancies. Williams (2010) argues that this invalidates research showing that measures of self-efficacy predict or mediate behavior, as it is possible that the effects are due to outcome expectancies.

Another distinction that has generated much discussion relates to the relationship of self-efficacy to the construct of perceived behavioral control in the theory of planned behavior. The author of the theory of planned behavior proposed that the differences were of negligible importance (Ajzen, 2002).

In light of these discussions, a distinction has been made between self-efficacy, considered to be confidence in their ability to engage in the behavior, and perceived controllability as perceptions of control over the behavior. It has been proposed that perceived behavioral control contains a mixture of both perceived control and self-efficacy. It is certainly the case that self-efficacy is much more predictive of behavior, such as binge–drinking, than is perceived control (see Cooke et al., 2014). However, there is evidence that commonly used measures of both self-efficacy and perceived behavioral control contain items that can be considered a mixture of both (Johnston et al., 2014).

Clarifying Conceptual Confusion

Taken as a whole, the criticisms that have been made of the conceptualization and operationalization of self-efficacy flag up that there is a greater need for clarity. Future measures of self-efficacy should be clearer whether they are concerned with confidence over ability to bring about behaviors or confidence in ability to bring about goals or other outcomes. Future measures of self-efficacy should avoid containing items that could be considered as perceived control. Most importantly, there is a need to develop measures that are not contaminated by also assessing outcome expectancies, so the unique effects of outcome expectancies and self-efficacy can be assessed.

Conclusion

Self-efficacy is a key construct in many theories of health-related behavior. It is consistently predictive of the performance of many of these behaviors. There is also some evidence that it plays a causal role for some of these behaviors, but further research is needed to provide stronger tests of this hypothesis. In particular, future research should focus on disentangling the role of self-efficacy and outcome expectancies in causing behavior, by using measures of self-efficacy that are contaminated by outcome expectancies.

Abstract

Self-efficacy, or perceived capabilities for learning or performing actions at designated levels, is grounded in Bandura's social cognitive theory that postulates reciprocal interactions among personal, behavioral, and social and environmental factors. Self-efficacy has been shown to influence various achievement outcomes, including motivation, learning, and self-regulation. Calibration, or how well self-efficacy corresponds to performance, can affect students' motivation and achievement. Self-efficacy is important for teachers as well as students. Areas for future self-efficacy research include assessment, developmental changes, cultural comparisons, and applications to learning with technology.

Self-efficacy refers to perceived capabilities for learning or performing actions at designated levels (Bandura, 1997). The operation of self-efficacy has been explored in various domains, including education, business, athletics, careers, health, and wellness. Researchers have found that self-efficacy influences individuals' learning, motivation, and self-regulation (Bandura, 1997; Pajares, 1996; Schunk and Pajares, 2009).

Self-efficacy is grounded in Bandura's (1986) social cognitive theory, which postulates reciprocal interactions among personal (e.g., cognitions, beliefs, skills, effects), behavioral, and social and environmental factors (Schunk, 2012). Social cognitive theory reflects a view of human agency in which individuals exert a large degree of control over the outcomes of their actions. They hold beliefs that allow them to influence their thoughts, feelings, actions, social interactions, and aspects of their environments. Thus, teachers who want to improve their skills enroll in courses and seek mentoring from more-experienced teachers. But at the same time, people are influenced by their actions and facets of their social environments. Teachers are apt to change their behaviors in response to advice from their mentors.

According to social cognitive theory, strategies for increasing well-being can be aimed at improving emotional, cognitive, or motivational processes, increasing behavioral competencies, or improving aspects of one's social and physical environments. Teachers are responsible for promoting learning among their students. Using social cognitive theory as a framework, teachers can improve their students' emotional states and correct their faulty beliefs and habits of thinking (personal factors), raise their academic skills and self-regulation (behaviors), and alter classroom features and social interactions (social and environmental factors) to ensure student success.

This article discusses the role of self-efficacy in education contexts. Following a review of self-efficacy theory, factors affecting self-efficacy and the measurement and prediction of self-efficacy are discussed. Applications of self-efficacy to self-regulation and teaching are explained. The article concludes with suggestions for future research.

Self-Efficacy Theory

Self-efficacy – a key variable in social cognitive theory – is hypothesized to influence behaviors and environments and in turn be affected by them (Bandura, 1986, 1997; Schunk, 2012). Students with high self-efficacy for learning are apt to engage in self-regulation (e.g., set goals, use effective learning strategies, monitor their comprehension, evaluate their goal progress) and create effective environments for learning (e.g., eliminate or minimize distractions, find effective study partners). In turn, self-efficacy can be influenced by the outcomes of behaviors (e.g., goal progress, achievement) and by inputs from the environment (e.g., feedback from teachers, social comparisons with peers).

Bandura (1997) postulated that people acquire information to gauge their self-efficacy from their performance accomplishments, vicarious (e.g., modeled) experiences, forms of social persuasion, and physiological indexes (Figure 1). Learners' performances provide the most reliable information for assessing self-efficacy because they are tangible indicators of one's capabilities. Successful performances raise self-efficacy, whereas failures can lower it, although an occasional failure (success) after many successes (failures) may not have much of an impact.

Individuals acquire much information about their capabilities through knowledge of how others perform (Bandura, 1997). Similarity to others is a cue for gauging self-efficacy (Schunk, 1995). Observing similar others succeed can raise observers' self-efficacy and motivate them to try the task because they may believe that if others can do it they can as well, although a vicarious increase in self-efficacy can be negated by subsequent performance failure. Persons who

Figure 1 Sources of self-efficacy information. Reproduced from Bandura, A., 1997. Self-efficacy: The Exercise of Control. Freeman, New York.

observe similar peers fail may believe they lack the competence to succeed, which may not motivate them to attempt the task.

Individuals also develop self-efficacy from the social persuasions (e.g., "I know you can do it") they receive from others (Bandura, 1997). Social persuasions must be credible and cultivate people's beliefs in their capabilities for successfully attaining outcomes. Although positive feedback can raise self-efficacy, the increase will not endure if students subsequently perform poorly (Schunk, 1995). Conversely, negative persuasions can lower self-efficacy.

Individuals acquire self-efficacy information from physiological and emotional states, such as anxiety and stress (Bandura, 1997). Strong emotional reactions to a task provide cues about anticipated success or failure. When students experience negative thoughts and fears about their capabilities (e.g., feeling nervous thinking about taking a test), those reactions can lower self-efficacy and trigger additional stress and agitation that help ensure the inadequate performance. Learners may feel more efficacious when they perceive that they are less anxious about academic outcomes.

Although self-efficacy is important, it is not the only influence on behavior. Social cognitive theory contends that no amount of self-efficacy will produce a competent performance when the necessary skills to succeed are lacking (Schunk, 1995). Students' *values* (perceptions of importance and utility of learning) also can affect behavior (Wigfield et al., 2004). Even students who feel highly efficacious in science may not take science courses that they believe are not germane to their goal of becoming a medical doctor. Also important are *outcome expectations*, or beliefs about the anticipated outcomes of actions (Bandura, 1997). Students typically engage in activities that they believe will result in positive outcomes and avoid actions that they believe may lead to negative outcomes, even when they feel efficacious about attaining the latter. Assuming requisite skills and positive values and outcome expectations, social cognitive theory predicts that self-efficacy is a key determinant of individuals' motivation, learning, self-regulation, and achievement (Schunk, 2012).

Self-efficacy can influence the choices people make and the actions they pursue (Bandura, 1997). Individuals tend to select tasks and activities in which they feel competent and confident and avoid those in which they do not. Unless people believe that their actions will produce the desired consequences, they have little incentive to engage in those actions.

Self-efficacy also helps determine how much effort students expend, how long they persist when confronting obstacles, and how resilient they are in the face of adversity. Students with a strong sense of self-efficacy approach difficult tasks as challenges to be mastered rather than as threats to be avoided. They set challenging goals and maintain strong commitment to them, heighten and sustain their efforts in the face of failure, and quickly recover their sense of self-efficacy after setbacks.

Distinctions with Other Variables

Other variables bear some conceptual similarity to self-efficacy (Schunk and Zimmerman, 2006). *Self-concept* refers to one's collective self-perceptions formed through experiences with and interpretations of the environment and influenced by reinforcements and evaluations by others (Shavelson and Bolus, 1982). Self-concept typically is viewed as hierarchically organized with a general self-concept on top and subarea self-concepts below, and multidimensional elements, such as self-confidence and self-esteem (Marsh and Shavelson, 1985; Schunk and Pajares, 2009). Self-perceptions of specific competencies influence subarea self-concepts (e.g., subject areas such as history and biology), which in turn combine to form the academic self-concept. Because self-efficacy involves perceived capabilities in specific areas, it should contribute to self-concept (Schunk and Pajares, 2009).

Self-esteem is a general affective evaluation of one's self that often includes judgments of self-worth (Schunk and Pajares, 2009). Like self-concept, it differs markedly from self-efficacy. Self-efficacy involves questions of can (e.g., 'Can I write this essay?'), whereas self-esteem reflects questions of feel (e.g., 'How do I feel about myself as a writer?'). One's beliefs about what one can do may bear little relation to how one feels about oneself, as seen in students with high self-efficacy for learning but low self-esteem because they are socially unpopular with peers.

Perceived control (or *agency*) also differs from self-efficacy. In Bandura's (1997) social cognitive theory, agency is the capability to control one's life events. One's system of personal agency includes self-efficacy and outcome expectations (discussed earlier). Although self-efficacy is a key component of personal agency (Bandura, 1997), it is not the only one. A responsive environment is necessary for self-efficacy to exert its effects. Students may feel self-efficacious for learning yet make no effort to do so because they believe that in their present environment learning will not be rewarded.

The notion of perceived control figures prominently in the theory of planned behavior (Ajzen, 1985, 1991). In this theory, the intention to engage in a behavior is its primary determinant. In turn, intention is affected by the perceive value of the outcome of the behavior, social norms, and pressures from others to perform the behavior, and perceived behavioral control (i.e., perceived difficulty in performing the behavior). The effects on behavior of variables such as self-efficacy are mediated through their influence on intention. Some research shows that perceived behavioral control corresponds closely to self-efficacy (Bandura, 1997). Furthermore, placing a heavy burden on intention as the primary determinant of behavior is risky, because there are many reasons why people do not always act based on their intentions. Education researchers have shown that self-efficacy can affect achievement both directly and indirectly through other variables (e.g., persistence, effort; Pajares, 1996; Schunk and Pajares, 2009).

Self-efficacy differs from *self-confidence*, or a general belief about one's capabilities that often does not specify the object of the belief (e.g., 'She is highly self-confident'). Self-efficacy is situated within Bandura's (1986) social cognitive theory and has a clear and specific meaning. Although self-confident individuals often are self-efficacious, there is no automatic relation between these variables. People who know they will fail at a task are highly self-confident but have low self-efficacy (Bandura, 1997).

Factors Affecting Self-Efficacy

Research has explored the effects of instructional and other classroom processes on self-efficacy (Schunk and Pajares, 2009). This research shows that instructional, social, and environmental factors inform students about their learning, and they use this information to assess their self-efficacy for continued learning.

At the outset of an activity, students' self-efficacy for learning is a function of their prior experiences, personal qualities (e.g., abilities, attitudes), and social supports. The latter include the extent that teachers, parents, and others encourage students to learn, facilitate their access to resources necessary for learning (e.g., materials, facilities), and teach them self-regulatory strategies that enhance skill development.

As students engage in learning activities, they are influenced by personal factors (e.g., goal setting, cognitive information processing) and situational variables (e.g., feedback, social comparisons). These influences provide students with cues about how well they are learning. Self-efficacy is enhanced when students believe they are performing well. Lack of success or slow progress will not necessarily lower self-efficacy if students believe they can perform better, such as by expending greater effort or using more-effective learning strategies (Schunk, 1995). In turn, self-efficacy enhances motivation, learning, self-regulation, and achievement.

Experimental research supports these hypothesized relations with students in different grade levels (e.g., elementary, middle, high, postsecondary), with diverse abilities (e.g., regular, remedial, gifted), and in different content areas (e.g., reading, writing, mathematics, computer applications; Schunk, 1995; Schunk and Ertmer, 2000). Some instructional and social processes that raise self-efficacy are having students pursue proximal and specific goals, exposing children to social models, providing students with performance and attri butional feedback, teaching students learning strategies, having learners verbalize strategies while they apply them, linking students' rewards to their learning progress, and having students self-monitor and evaluate their learning progress. These processes differ in many ways, but they all help to inform students of their learning progress, which raises self-efficacy.

Prediction of Education Outcomes

Research shows that self-efficacy for learning or performing tasks correlates positively and significantly with subsequent achievement on those tasks (Pajares, 1996; Schunk and Pajares, 2009). Correlations between academic self-efficacy and performance in investigations in which self-efficacy corresponds closely to the criterion task have ranged from .49 to .70; direct effects in path analytic studies have ranged from $\beta = .349$ to .545 (Pajares and Urdan, 2006). Self-efficacy explains approximately 25% of the variance in the prediction of academic outcomes beyond that of instructional influences. Using meta-analytic procedures, Multon et al. (1991) found that self-efficacy related to academic performance ($r_\mu = .38$) and accounted for 14% of the variance. Stronger effects were obtained with highly congruent self-efficacy and skill measures. Self-efficacy also correlates positively with indexes of self-regulation (e.g., goal setting, strategy use, performance monitoring; Schunk and Pajares, 2009).

Based on findings from meta-analysis, Brown and Lent (2006) reported that self-efficacy is a significant predictor of education interests and mediates the relation of prior performance and ability measures to interests. Using meta-analysis with self-beliefs that include self-efficacy and more-global measures, such as self-concept, Valentine et al. (2004) found a small positive influence of self-beliefs on achievement and that the influence was stronger with self-beliefs specific to academic domains (e.g., self-efficacy).

Researchers have used causal models to test the predictive and mediational power of self-efficacy. Using path analysis, Schunk (1981) found that self-efficacy exerted a direct effect on children's achievement and persistence in mathematics. Pajares and Kranzler (1995) demonstrated that mathematics self-efficacy has as powerful and direct effect on mathematics performance as does cognitive or mental ability. Zimmerman and Bandura (1994) found that self-efficacy affected achievement directly as well as indirectly through its influence on goals. Schunk and Gunn (1986) found that children's mathematical achievement was directly influenced by use of effective strategies and self-efficacy. Relich et al. (1986) showed that self-efficacy exerted a direct effect on achievement and that instruction had both a direct and an indirect effect on achievement through self-efficacy (Figure 2).

Self-Efficacy Assessment

The earliest self-efficacy studies were conducted in clinical settings. Bandura et al. (1977) administered a self-efficacy and a behavioral test to adults with snake phobias. The test items consisted of progressively more threatening encounters with a snake (e.g., touch it, allow it to sit in one's lap). For the self-efficacy assessment, participants designated which tasks they felt they could perform and rated how sure they were that they could perform the tasks they felt they could perform. To measure generality, participants rated the same tasks with a type of snake different from the type used on the test. This is a microanalytic research methodology; self-efficacy and skill were assessed at the level of specific tasks.

Figure 2 Self-efficacy effects on achievement. Reproduced from Relich, J.D., Debus, R.L., Walker, R., 1986. The mediating role of attribution and self-efficacy variables for treatment effects on achievement outcomes. Contemporary Educational Psychology 11, 195–216.

Participants were not asked for a general rating of how well they felt they could deal with snakes.

Early education studies used a similar methodology. Schunk (1981) gave children with low mathematical skills self-efficacy and skill tests. For self-efficacy, children were shown pairs of long-division problems; the two problems within each pair were comparable in form and difficulty. For each pair, they judged how certain they were that they could solve problems of that type. For the skill test, children attempted to solve problems that corresponded in form and difficulty to those on the self-efficacy test.

Since Bandura's (1977) initial formulation of self-efficacy, researchers have moved beyond his definition of self-efficacy as a domain-specific variable and assessed self-efficacy at more-general levels with such items as, "How well can you get teachers to help you when you get stuck on school work?" and, "How well can you study when there are other interesting things to do?" (Schunk and Pajares, 2009). To arrive at these types of judgments, students must integrate their perceptions across different situations (e.g., involving mathematics, science, social studies, and so forth).

There is some research evidence for a generalized sense of self-efficacy (Smith, 1989). Certain education conditions might foster it. School curricula are structured for positive transfer; for example, learning how to divide requires knowing how to estimate, subtract, and multiply. Students who perform well in mathematics might approach division with higher self-efficacy than those who have encountered difficulties.

Even in the absence of specific curricula structure, generalization also might occur when students believe that the new learning will require skills that they previously have mastered. Thus, writing a research paper requires identifying a topic, conducting a literature review, synthesizing and organizing information, and drawing conclusions. Students likely have used these skills to write papers in English. Students who feel competent in the requisite skills may have higher self-efficacy for writing a research paper than those who question their capabilities.

Finding evidence of generality would not refute the subject specificity of self-efficacy, but it is important to determine how students weigh and combine efficacy information to arrive at generalized judgments. Developmental factors may be an issue, because we should expect that with development students should be better able to assess their capabilities in component areas and determine the types of skills needed to succeed.

Calibration

The issue of *calibration*, or how well self-efficacy relates to actual performance on the corresponding tasks (Schunk and Usher, 2011), has been studied by researchers. When people judge that they are capable of performing a task and then perform it, or when they judge that they are incapable of performing it and cannot perform it, they are well calibrated because self-efficacy accurately predicts performance. Conversely, when people judge that they are capable of performing a task but do not perform it, or when they judge that they are incapable of performing a task but then perform it, they are poorly calibrated because of the lack of correspondence between self-efficacy and performance.

Calibration involves intentions, as stressed by the theory of planned behavior (Ajzen, 1991). In discussing implementation intentions, Gollwitzer and Sheeran (2006) noted that even with positive attitudes and social norms people may not perform behaviors if they doubt their capabilities of doing so successfully.

Calibration is educationally important. Motivation suffers when students who overestimate their capabilities perform poorly. Although self-efficacy that slightly exceeds what one can do is desirable because such overestimation can raise effort and persistence (Bandura, 1997), recurring overestimation can lead to continued failure with resulting decrements in students' motivation and learning.
